THE LANCET

Journal of British and Foreign Medicine, Surgery, Obstetrics, Physiology, Chemistry, Pharmacology, Public Health, and News.

IN TWO VOLUMES ANNUALLY.

Vol. CCXVIII.

Vol. I. for 1930.

ONE HUNDRED AND EIGHTH YEAR.

EDITED BY

R SQUIRE SPRIGGE, M.D. Cantab., F.R.C.P. Lond., F.R.C.S. Eng.,

AND

ERT MORLAND, B.Sc., M.B. Lond., M.D. Berne.

LONDON
LISHED BY THE PROPRIETORS, THE LANCET LIMITED, NO. 7, ADAM STREET, ADELPHI, W.C., IN THE COUNTY OF LONDON, AND PRINTED BY HAZELL, WATSON & VINEY, LTD., 52, LONG ACRE, W.C.2.

MCMXXX.

REFERENCES AND ABBREVIATIONS

Readers in search of a given subject will find it useful to bear in mind that the references are in several cases distributed under two or more separate but nearly synonymous headings—such, for instance, as Brain and Cerebral, Heart and Cardiac, Liver and Hepatic, Child and Infant, Goitre and Thyroid, Diabetes, Glycosuria and Sugar, Eye, Ophthalmic, and Vision, Lunacy and Mental Disease, Arsenobenzol and Salvarsan, &c., &c., and that regional headings are more frequently used than pathological. Institutions and Corporations with the right to the prefix Royal will be found under that prefix, with the exception of Hospitals, which will be found under that heading; and Medical Societies, which are separately indexed under Societies. All Universities are indexed under the word University. (A.) = Annotation, (C.) = Correspondence, (N.I.) = New Inventions, (L.A.) = Leading Article, (M.L.) = Medico-legal, (M.T.T.) = Modern Technique in Treatment, (O.) = Obituary, (P.I.) = Parliamentary Intelligence, (R.) = Review, (R. and A.R.) = Reports and Analytical Records, (A.D.) = Clinical Interpretation of Aids to Diagnosis, and (N.P.) = New Preparations.

CONCORDANCE

To enable the reader to determine at a glance the date and serial number of the issue of THE LANCET containing the required page reference.

INDEX TO VOLUME I., 1930.

A

Abdominal tumours, pressure caused by (G. W. Theobald), 901
Abel, A. Lawrence, on acetylcholine in relation to abdominal surgery, 459
Abercrombie, R. G., Physical treatment centres (C.), 883
Aberdeen, a brick hospital in, 381; Chair of Medicine in (A.), 37
Aberdeenshire cottage hospital, an, 1260
Allett, Richard, A Course in Physics (R.), 358
Abortion, criminal, heavy sentences for (M.L.), 468; in Russia, 1425
Abrahams, Adolphe, the human machine, 474
Absinthe and absinthe drinking in England (C. W. J. Brasher), 944, 1271
Accidents at Manchester, 496; at Sheffield, 236; in coal mines, fatal, 1432; motor, the cost of, 76; increase of (P.I.), 599; road (A.), 1246; hospitals and (P.I.), 267; 305, 496, 828, 1092, 1142, 1339, 1435; in Ireland, 828, 1092; (A.), 1359; (P. Granville Edge), 1362
Accounts, delay in rendering, 158
Aceto-acetic acid, relation of, to diabetic coma, and the cause of death (E. C. Dodds and J. D. Robertson), 852
Acetylcholine in relation to abdominal surgery, 459
Achylia gastrica, ætiological relationship of, to pernicious anæmia (W. B. Castle, W. C. Townsend, and C. W. Heath), 1062
Actinomycosis in man and animals (A.), 251
Adami, J. George: A Memoir (Marie Adami) (R.), 968
Adams, death of Mr. Harry Percy, 820
Addison, Dr. Christopher, appointed Minister of Agriculture and Fisheries, 1304
Adeney, W. E., Principles and Practice of the Dilution Method of Sewage Disposal (R.), 245
Adipositá Patologiche, Le (Giovanni Poggio) (R.), 466
Adler, Alfred, Problems of Neuroses (R.), 191
Adolescent, significance of the home in the personality and character development of the, 1149
Adrenalin and hypoglycæmia (A.), 1418
dvertisement of medicines in Holland, 168
nexa, treatment of diseases of the, 1206
vertising, acceptable, 1382
vick-le-Street, M.O.H.'s report, 1372
ca, West, Health in (D. B. Blacklock) hadwick lecture), 843
iew, Edward Dalton (O.), 1212
ert and Victoria Hospital Aid Society, 303
cohol, action of, upon the blood-sugar in diabetes mellitus (T. C. Hunt), 121; s an economic factor (A.), 148; as a nental hygiene problem, 1148; orbital injections of (A.), 367
dehyde reaction, Ehrlich's, 386
lexander, Frans, on mental hygiene and criminology, 1148
Alexander, G. F., A new capsule forceps (N.I.), 1129
Alexandra Rose Day, 386, 498
Alkalosis in congenital hypertrophic pyloric stenosis (Montague Maizels, Catherine B. McArthur, and Wilfred W. Payne), 286
Allan, H., and Dickens, F., Zondek and Aschheim tests for pregnancy, 39
Allergy, a course in (A.), 1084
Altitudes, living at very high, and maintenance of normal health (J. Argyll Campbell), 370
Ambulance work in Ireland, 1368
America, impressions of psychiatry in (Edward Mapother), 848
American medical students and study in Britain, 1241
Amputations and their relation to the artificial limb, discussion on, 807; (L.A.), 814; (C.), 1010
Amytal (A.), 1302
Anæmia, liver in (A.), 586; of alimentary origin, liver therapy in (Daniel T. Davies), 292; of pregnancy and vitamin deficiency in India (A.), 702; pernicious (L. S. P. Davidson and G. L. Gulland) (R.), 517; ætiological relationship of achylia gastrica to (W. B. Castle, W. C. Townsend, and C. W. Heath), 1062; effect of liver on nervous lesions of (A.), 92; gastric defect in (C.), 160; further advances in the pathology of (A.), 1080; not responding to liver treatment, case of (A. C. Hampson), 22; response obtained in healthy pigeons by the administration of substances effective in (Janet M. Vaughan, Gulli Lindh Muller, and George R. Minot), 1062; type of, following erythræmia (Harold Avery), 312; (C.), 483
Anæsthesia and Anæsthetics (F. S. Rood and H. N. Webber) (R.), 631; Dental Local (Outlines of Dental Science, Vol. XII.) (John James) (R.), 28; ethylene, 1017; (A.), 1027; for thoracoplasty in pulmonary tuberculosis (I. W. Magill), 295; general, by intravenous injection of ethyl alcohol (Julien D. Constantin), 1393; in thoracic surgery, discussion on, 352; local: Anæsthésie locale en oto-rhino-laryngologie (G. Canuyt and J. Joubiot) (R.), 1296; technique of, 81; mentality and (L.A.), 193; (C.), 322; spinal (C.), 210, 211, 261, 323, 377; 573; (C.), 591; Cæsarean section under (J. W. Burns), 1012; (C.), 1095, 1376; criticism of Pitkin method (E. Falkner Hill), 121; 573; high (A.), 145; in difficult midwifery, 1236; new methods in (A.), 587
Anæsthetic apparatus, an, 896; gas-oxygen as a routine (A. H. Macklin), 1231; (C.), 1375; work, barbituric acid compounds in (A.), 473
Anæsthetics, explosion of (A.), 1301; in labour, use of (A.), 253
Analgesia, spinal, with spinocain, 573
Anatomie, Lehrbuch der Systematischen (Julius Tandler) (R.), 918
Anatomy, Applied (Gwilym G. Davis), 8th ed. rev. George P. Muller (R.), 139; Gray's (T. B. Johnston ed.), 24th ed. (R.), 1409
Anatomy and Physiology, Text-book of (Jesse F. Williams), 3rd ed. (R.), 918
Anderson, J., How to Stain the Nervous System (R.), 1239
Anderson, John, on cutting currents, 485
Anderson, V. V., on the contribution of mental hygiene to industry, 1149
Anderson-Stuart, Surg. Lt.-Commr., death of, 421
Andrewes, C. H., and Carmichael, E. Arnold, Presence of antibodies to herpes virus in post-encephalitic and other human sera, 857
Anencephalic fœtus, an, 135
Aneurysm, gluteal, case of (A. D. Charters), 451; of the heart, case of (W. S. Russell Thomas), 405
Angina pectoris and coronary disease (Douglas Hubble), 908; (C.), 1093, 1154; pathogeny of (A.), 921
Angines Aigües, Le Diagnostic des (A. B. Marfan) (R.), 1076
Angove, H. S., and Douthwaite, A. H., Remedial exercises in the treatment of pulmonary disease, 346
Animal Diseases Research Institute: appointment of director, 327
Animal nutrition, Prof. Brailsford Robertson and his work for (A.), 365
Animism, Magic and the Divine King (Géza Róheim) (R.), 812
Anspach, Brooke M., Gynæcology, 4th ed. (R.), 920
Anthracosis (P.I.), 493; Home Office and (P.I.), 1214
Anthrax, death from (P.I.), 435; Home Office and (P.I.), 1214; scientific inquiry on (P.I.), 836
Antiseptic for internal use, a new (A.), 759
Ants, a plague of, 1268
Apples for dysentery (A.), 526; (C.), 672
Appointments, weekly lists of, 56, 110, 165, 217, 272, 329, 385, 437, 497, 545, 605, 671, 731, 783, 839, 893, 943, 995, 1052, 1104, 1160, 1217, 1270, 1322, 1379, 1436
Arafa, M. A., and Biggam, A. G., Effect of rivanol in treatment of amœbic dysentery, 1335
Arctic, a hospital in the, 732
Armit, Henry William (O.), 661
Army doctors, dearth of, 54 years ago, 386; health of the, in 1928 (A.), 249; Medical Service (P.I.), 727, 779; venereal disease in the (P.I.), 269
Arnaud, François, Thérapeutique, Pharmacologie et Matière Médicale (R.), 1410
Arris and Gale lecture, 673
Arsenic, preservative action of (A.), 1244
Arterial calcification, new treatment for (Vlad. Mladejowsky), 917
Arteries, diseased, detection of, by uroselectan, 829
Arthritis and Rheumatoid Conditions (Ralph Pemberton) (R.), 1238; gonococcal, 530
Arthroplasty, Mobilisation of Ankylosed Joints by (W. Russell MacAusland and Andrew R. MacAusland) (R.), 413
Artificial limbs, amputations and, discussion on, 807; (L.A.), 814; (C.), 1040
Asbestosis, pulmonary (W. Burton Wood and S. Roodhouse Gloyne), 445; (A.), 701; (L.A.), 870
Aschoff, nodule, the, in rheumatic pneumonia (A. D. Fraser), 70
Ash, W. M., on mental deficiency and lunacy in relation to public health, 864
Askins, R. A., Practice in Southern Rhodesia (C.), 1094
Asthma Research Council, scientific meeting, 1291
Asthmatic reaction in children (A.), 923
Astley Ainslie Institution for Convalescence, Edinburgh, 1204
Asylums Research laboratory, the first (A.), 145; (C.), 213
Athletics in schools (Lancelot R. Lempriere), 679; discussion on, 690; (C.), 773, 831
Austin, T. A., and Lane, T. J. D., Three new instruments for obtaining and working fascial sutures, 622

AUSTRALASIA, CORRESPONDENCE FROM.—Crippled children, training of, 936—Infant welfare centre in Australia, 591—Sharks, man-eating, 936—Spider bite, poisonous, 591—Sydney, appointments at, 591; post-graduate work in, 936

Australasia, surgery in, 1253
Australasian College of Surgeons: annual general meeting in Melbourne, 1253; annual state meeting in Queensland, 136
Australia, maternal mortality in (A.), 418
Australian school, a new (A.), 1195
Austria, child welfare in (A.), 35
Austrian thaumaturgist, an (A.), 196
Autonomic nervous system, the (Walter B. Cannon) (Linacre lecture), 1109; function of the (L.A.), 1133
Avertin, anæsthesia (C.), 1264; as a basal narcotic in laryngology, 1404; estimation of dangers of, 438; in gynæcology, an experience with (James Young), 1177
Avery, Harold, A pernicious type of anæmia following erythræmia, 342
Avicenna, The Canon of Medicine of (O. Cameron Gruner) (R.), 465; 1438
Aykroyd, W. R., on functional night-blindness due to vitamin deficiency, 824

B

Baby Week Challenge Shields, 76; Council, National, annual meeting of, 672
Bach, Francis, The blood picture and its clinical significance (C.), 883
Back, end-results of manipulation of the (E. W. Riches), 957
Back, Ivor, on defæcation, 459; on the significance of obstruction of colon or rectum, 458
Backache, cervicitis and (A.), 1136
Bacteriology in Relation to Medicine, System of (Medical Research Council), Vol. II. (R.), 516
Bacteriology and Immunity, Principles of (W. W. C. Topley and G. S. Wilson) (R.), 26
Bacteriophage and lysogenic bacteria (A.), 523; in cholera, 1031
Bailey, Hamilton, Demonstrations of Physical Signs in Clinical Surgery, 2nd ed. (R.), 630
Bain, C. W. Curtis, and East, C. F. T., Recent Advances in Cardiology (R.), 1075
Baird, D., and Cruickshank, R., on vaginal flora in pregnancy, 1407; on value of Dick test in pregnancy, 1406

lephantiasis treated by protein shock (G. Carmichael Low and D. Strangways Dixon), 72
liason, E. L., and others, Surgical Nursing (R.), 631
llis, Rowland H., and Hall, I. Walker, Sheep-dipping and the shepherd, 448
llison, J. B., Fatal case of diphtheria with cerebral thrombosis, 1345
llman, P., on diagnosis at a tuberculosis dispensary, 628
Embryology, The Essentials of Human (Gideon S. Dodds) (R.), 139
Emerson, Charles Phillips, Essentials of Medicine, 9th ed. (R.), 1351
Emerson, Haven, on mental hygiene as a public health problem, 1095
Emigrants to Canada, rejection of, on medical grounds (P.I.), 540
Emphysema treated by mechanotherapy (C.), 51, 105, 160
Encephalitis in the acute specific fevers (L.A.), 1191; post-vaccinal (A.), 525
Encephalomyelitis, disseminated, following small-pox (Arthur G. Troup and E. Weston Hurst), 566; (C.), 661, 723, 774
Endocrine glands, secretory disorders of, associated with eye diseases, 823
Endometrial autotransplants in the rabbit, 1127
Endometrioma, a case of, 1127
Energen Bismeal Nutrient Breakfast Food (R. and A.R.), 86
English, current, 1052
Enteric fevers, quantitative serum diagnosis of (A. Felix), 505; infection, blood culture in diagnosis of (C.), 1316, 1433
Epilepsie, L': Conceptions actuelles sur sa pathogénie et son traitement (Ph. Pagniez) (R.), 518
Epilepsy, nervous semiology in (L.A.), 1297
Epsom College (A.), 1192; St. Anne's scholarship, 1378
Erbolin (N.P.), 498
Erdmann, Rhoda, Praktikum der Gewebepflege oder Explantation besonders der Gewebezüchtung, 2nd ed. (R.), 1409
Ergosterol, irradiated, damage from, 42
Ergosterols, irradiated (C.), 831; 999
Erythema multiforme, ætiology of (A.), 147
Esperanto and medicine, 842
Essex County Sanatorium, opening of, 998
Essex Public Medical Service, annual report, 1161
Ethyl alcohol, intravenous injection of (C.), 831
Ethyl chloride inhaler (Gerald Moriarty) (N.I.), 25
Ethyl petrol, the acquittal of (A.), 820
Ethylene anæsthesia, 1017; (A.), 1027
Eugenics Education Society, bequest to, 1048
Evans, C. Lovatt, and Hartridge, H., ed. and rev. Starling's Principles of Human Physiology, 5th ed. (R.), 138
Evans, Geoffrey, on high blood pressure, 861
Evans, Herbert M., and Swezy, Olive, The Chromosomes in Man (R.), 465
Everidge, John, on technique and results of prostatectomy, 1185
Evolution, inexorability of law of, as manifested in modern medicine (Sir Arthur Keith), 1053; of the Earth and Man (by twelve authors) (R.), 360
Examination papers, specimen, 841
Excreta examination device (David A. Herd) (N.I.), 578
Exercises, remedial, in the treatment of pulmonary disease (A. H. Douthwaite and H. S. Angove), 346
Exophthalmic goitre, chemistry of the blood, and condition of bones in, 955
Exophthalmos, unilateral, case of, 1406
Experiments on living animals, operative (P.I.), 269
Eye, Affections of the, in General Practice (R. Lindsay Rea) (R.), 576; amnion bands and the, 825; clinical application of newer conceptions in the physiology of the (W. S. Duke-Elder), 4; Diseases of the (Sir John Parsons), 6th ed. (R.), 867; disorders of secretion of endocrine glands associated with, 823; in China (A.), 419; lesions of the, interpretation of reports on (S. H. Browning) (A.D.), 255, 311; Pathology of the (Jonas S. Friedenwald) (R.), 300
Eyeball, perforating injuries of the (A.), 363; (J. Herbert Fisher) (Hunterian lecture), 787
Eyes in childhood, care of the (L.A.), 1242; position and movements of the, some factors controlling, 823
Eyster, J. A. E., Clinical Aspects of Venous Pressure (R.), 968

F

Face powder, a dermatitis from (C.), 484
Factory clinic, a (C.), 378; inspectorate (P.I.), 600; service, medical men in the (P.I.), 492
Fagan, Sir John, death of, 640, 772, (O.), 833
Fairfield, Letitia, on gonorrhœa from the medico-legal point of view, 966
Fairley, Keith D., Cholelithiasis as a sequel of blackwater fever, 1395
Falmouth, new hospital for, 1074
Fascial insertions of muscles, injuries of (B. S. Nat), 749; sutures, three new instruments for obtaining and working (T. J. D. Lane and T. A. Austin), 622
Faulds, Henry (O.), 781
Featherstone, H., and Whitehouse, Beckwith, Cæsarean section under spinal analgesia (C.), 1095
Fee, Archibald R. (O.), 485
Fee-cutting in pathological services (C.), 1093
Felix, A., Quantitative serum diagnosis of enteric fevers, 505
Fellowship of Medicine and Post-Graduate Medical Association, courses, lectures, and demonstrations, 90, 543, 944, 994, 1135, 1248
Ferguson, Fergus R., and Rees, W. Esmond, Cerebro-spinal metastases from unsuspected pulmonary carcinoma, 738
Ferrée, C. J., The Soya Bean and the New Soya Flour (R.), 920
Fertility, motility of spermatozoa as a test of (A.), 637
Fibroids associated with congenital recto-vulval fistula, Cæsarean hysterectomy for (A. M. Claye), 963
Fibrositis (E. B. Clayton and J. L. Livingstone), 1420
Fielding, Michael, Parenthood: Design or Accident? 2nd ed. (R.), 1240
Filtrable viruses, 529; immunisation against (A.), 1025
Findlay, G. M., Cutaneous papillomata in the rat following exposure to ultraviolet light, 1229; on tropical diseases arising from dietetic deficiency, 79
Fire at a fever hospital, 1367
First-aid by railwaymen, 896; in industry, 828
"Fisgard" (C.), 498
Fish, hygienic methods of handling (P.I.), 436; stale, sale of (P.I.), 494
Fisher, J. Herbert, Perforating wounds of the eyeball (Hunterian lecture), 787; on secretory endocrine disorders associated with eye diseases, 823
Fisher, R. A., Statistical Methods for Research Workers, 4th ed. (R.), 1019
Flat-foot, spasmodic, discussion on, 513
Flemming, Arthur L., The mechanism of pulmonary collapse (C.), 1265
Fletcher, William, on typhus-like fevers of unknown ætiology, 750
Flies prefer white light, 944
Flogging, punishment by (P.I.), 380, 436
Flood, G. M., Sewage Disposal from Isolated Buildings (R.), 245
Floods, Thames, and public health (P.I.), 50
Florence, Lella Secor, Birth Control on Trial (R.), 919
Flour, chemically treated, importation of (P.I.), 890
Flower, Norman, Traction frame for fractures of leg (N.I.), 1240
Fœtal heart beat, the: an obstetrical experiment (C. Russell Corfield), 803
Fœtor oris of tonsillar origin and certain bacilli causing it (Sir Aldo Castellani), 623
Food Education Society, 705; or drug? (A.), 475; (C.) 535, 594; poisoning, causes of (L.A.), 1354; storage of (A.), 1417; Values in Practice (Ethel M. Dobbs) (R.), 1076
Football competitions for hospitals, 1155
Foot-rest, bed (Hugh F. Ealand) (N.I.), 357
Forceps, a new capsule (G. F. Alexander) (N.I.), 1129
Foreign bodies recovered from the air and food passages, 1403
Foreign body, an inhaled, extruded through the chest wall (E. Hayling Coleman and Vincent Patrick), 77; (C.), 222
Formulary, Lippincott's Pocket, 2nd ed. (R.), 414
Formulas, a declaration of (A.), 306
Fornet, W., Unbekanntes von Insulin (R.), 1351
Forrester, A. T. W., Psittacosis (C.), 323, 484
"Fouadin" treatment of bilharziasis with a new compound (M. Khalil and M. H. Betache), 234
Fournier, death of Dr. Louis, 256
Fowler, Robert H., Tonsil Surgery (R.), 967

Purvis Oration

ENTITLED

THE DUMPING GROUND OF NEURASTHENIA.

Delivered before the West Kent Medico-Chirurgical Society on Dec. 13th, 1929,

BY SIR E. FARQUHAR BUZZARD, BT., K.C.V.O., M.D. OXON., F.R.C.P. LOND.,

CONSULTING PHYSICIAN TO ST. THOMAS'S HOSPITAL; REGIUS PROFESSOR OF MEDICINE IN THE UNIVERSITY OF OXFORD.

TAKEN as a whole we doctors carry on our trade in an honourable fashion and are imbued with a genuine desire to cheat neither our clients nor ourselves; but it can hardly be denied that the label of neurasthenia is often used in order to evade a duty—the duty imposed on us to declare a correct diagnosis. Whether such action should be regarded as a crime or only as a pardonable misdemeanour is a moral question I do not propose to discuss; the object of my discourse is to show that it is not good business.

The label of neurasthenia is a bad business proposition for two reasons. In the first place it conveys little or no pathological meaning to your own mind; in the second place it gives your patient the impression that he is suffering from a disease the cause, course, and outcome of which are equally mysterious to both of you. "Then, it is only nerves?" he will say to you. And you won't know what answer to give. Whether it is yes or no or a compromise, it is given with a hesitancy which can only add to the patient's depression and must eventually lead to loss of confidence. And that is bad business because, contrary to what is generally supposed and to what might be expected, we are not really judged so much by the results of our treatment, which is fortunate, but by our knowledge and understanding of our patients and their illnesses. The quack must perforce depend on his ability to cure and, therefore, always and inevitably fails in the long run to keep the position he attains by means of a wealth of promise and a poverty of knowledge. *We* must rely on our ability to detect the origin of an illness, on our acquaintance with its natural progress and natural result, and on our experience of how these may be influenced by treatment, if we are to preserve our rôle of trusted guide, rather than that of healer, in times of trouble. This is an axiom which holds good in all fields of medicine, but which has peculiar difficulties as well as outstanding importance in its application to the handling of neuroses or functional nervous disorders.

It is to these difficulties and the mode of their origin that attention must be drawn if an attempt to tidy up the dumping-ground of neurasthenia is to meet with any success.

NATURE OF FUNCTIONAL DISORDERS.

Thirty years ago those interested in disorders of the nervous system were chiefly concerned with the study of structural changes as revealed in the human body after death, and with the determination of physical signs denoting the presence of such structural changes during life. Disorders of the nervous system at that time were either organic or functional, and in order to decide to which category a particular disorder belonged it was only considered necessary to determine the presence or absence of organic signs. In the absence of organic signs the condition was regarded as functional, and little further interest was taken in its pathology. The literature of the period I refer to is full of dissertations on the value of various signs of organic disease revealed during the examination of patients, especially in relation to the reflexes, and the work which was carried out was of great and lasting importance. Since that time, however, considerable advances have been made in neurology, in psychopathology, in endocrinology, in bacteriology, and in other branches of medicine, many of which bear upon the *nature* of functional nervous disorders and therefore upon their treatment.

In neurology, for instance, we are no longer altogether dependent on the presence of physical signs for a diagnosis of organic disease. We recognise disorders of function, as revealed by a patient's complaints, as equally good evidence of organic disease, and we rely therefore on our ability to discriminate between symptoms which suggest organic disease and those which suggest disorders of mind, disorders. [illegible] that term in preference to that of "functional much attention and give much time [illegible] obliged to pay of patients and to cultivate the arts of listening and of cross-examination. In other words, we have come to study illnesses in longitudinal section more than in cross-section as was the custom at an earlier period. The same trend has been manifest in the domain of psychopathology where Freud, using the historical or longitudinal method of investigation, has led the way in exposing the source and development of many disorders of the mind, thus throwing much-needed light on the causal factors underlying the neuroses and psychoneuroses. Although we may not be ready to support the Freudian school in all its contentions and conclusions, there can be no doubt that we owe it a great debt of gratitude for clearing up many obscurities, and not least, and this as you will see has much bearing on my subject for to-night, for enabling us to distinguish between those mental disorders which are amenable to psychotherapy and those which are not. The importance of this step in dealing with the group of cases labelled "neurasthenia" is difficult to exaggerate.

As a natural corollary to what is sometimes termed the new psychopathology the physician can no longer be content with a diagnosis of functional disorder based on the absence of signs or symptoms of organic disease. He must go further, as he would in a case of organic disease, and endeavour to establish its pathology: in other words, to trace the morbid process back to its causal origin. That this quest is often difficult and sometimes unsuccessful, as in organic disease, does not absolve him from its pursuit, and, whatever the result, the process is likely to promote that favourable atmosphere of confidence between doctor and patient so essential for any therapeutic measures that may follow.

CLINICAL LIMITATIONS OF BIOCHEMISTRY.

Although it cannot be doubted that the obscurity of neurasthenic problems has been lightened by the advances in neurology and psychopathology I have referred to, the same cannot be stated with equal truth in regard to other branches of medicine such as endocrinology and bacteriology. On the contrary, Freudian doctrines have produced a reaction in the minds of many medical men which has taken the form of a desire to ascribe all mental disorders, including neurasthenia, to some physical or chemical agent the result of disturbed glandular secretions, of septic tonsils or teeth, of intestinal stasis or infection, or of a blood pressure which is too high or too low. In accepting such theories the post hoc propter hoc argument has been utilised with little critical judgment and the frequency with which all these morbid conditions are found unassociated with mental disorders has not been given sufficient weight. On the other hand, it has been often demonstrated that when the removal of teeth, tonsils, or an appendix has failed to cure an anxiety neurosis an attack on the position through psychological channels has brought complete and lasting relief. While it is the duty of a doctor in attendance on a neurasthenic patient to look after his or her physical health, he is guilty of culpable negligence if he overlooks or ignores the mental factors to which the patient's miserable condition is primarily due. This is a subject on which it is difficult the interests of the patient but because a doctor's credit or discredit often hangs on the manner in which he tackles the problem of depression. Many of these patients are of necessity and indeed often better treated in their own homes, provided that they can there obtain all necessary care and attention, but the situation must be clearly explained to their relatives, who must be ready to coöperate with the doctor and to realise the scope and limitations of his treatment. Let me again quote Dr. Ross in this connexion :—

> "Nothing, so far as is known, will shorten the attack, but much can be done to make it safe and comfortable for the patient. . . . It is, moreover, an illness where we must not always expect to gather the fruits of our labour. We may sow and another man reap and obtain much credit which in no way belongs to him. If compensation is necessary to the doctor, he will get it often from some other man's cases. After many months of unwearied attention to a patient suffering from the disease, it often happens that the friends of the patient think a change desirable; they have been told by so many people that this, that, or the other person is the man for such cases, and perhaps soon after the change the long-looked-for cure takes place. But there is an interchange of luck in this respect and the writer has often received credit for the recovery when all that had happened had been that he was the man in attendance at the end. Such undeserved praise or dispraise comes from the friends; the patient always knows better, and there is no class of patient from whom more sincere gratitude is obtained than from a depressive.
>
> "The first essential is that the patient should be under care, and that he should be visited frequently, it may be daily or only every other day. His history should be taken in the same way as was advised for that of the neurasthenic, and the physical condition thoroughly investigated. The patient may be asked whether he has had any anxieties; if he says not, this statement should be accepted without question. It is essential that nothing in the nature of psychological probing should be done to a patient in this group. He will without doubt be a person who is, for the time at any rate, filled with the sense of inferiority, and probing into his past may tend greatly to increase this, and turn a mild case into one of great gravity. Such a procedure may certainly turn a non-suicidal patient into one where the danger is present."

With this grave warning I am entirely in agreement; by itself it forms a strong argument in favour of making a correct diagnosis and an equally potent reason against the use of any form of psycho-analysis in the treatment of the autonomous depressive. It must be remembered that the majority of suicides are committed by these patients and especially by those who suffer from the disease in a moderately severe form. The danger of suicide by a neurasthenic is comparatively negligible in spite of the evidence given in coroners' courts.

For the rest, the treatment of the depressive is largely symptomatic. He is easily tired and certainly made worse by fatigue. His sleep is generally disturbed during a considerable part of his illness and sedative drugs are often indicated and valuable, especially when given in the early hours of the morning, the time at which the patient is inclined to wake and to be at his worst. Light occupation is beneficial but many sufferers are unable to settle down to anything and their restlessness is often distressing.

But perhaps the most important part of the treatment is the daily visit of the medical attendant who must be patiently content to listen every time to the same miserable story and to repeat his assurance that the patient's condition is a well-recognised illness and one which invariably ends in complete recovery. One fine day the doctor may find the patient quite well, the cloud lifted, and peace of mind restored. The recovery is not always so dramatic; it may be gradual and sometimes the cloud may lift for 24 hours and fall again. It is impossible to predict and it is generally wise not to make the attempt.

AN EVERYDAY PROBLEM.

My attack on the Dumping Ground is fading away. It began with the creditable intention of turning over, sifting and criticising everything with neurasthenic pretensions. I am aware that I should have found many oddities of interest in the process. There would have been revealed cases of unsuspected organic disease, of mild encephalitis, and of early general paralysis. Here and there an incipient dementia præcox or a compulsion neurosis might have come to light. But in very truth my objective was to present the differentiation of the anxiety neurosis from the manic-depressive in the plainest colours, and to show that such differentiation is not a matter of mere academic snobbishness but an everyday problem of outstanding importance to all who practice medicine.

An Address

ON THE

CLINICAL APPLICATION OF THE NEWER CONCEPTIONS IN THE PHYSIOLOGY OF THE EYE.

Delivered on receiving the William McKenzie Memorial Medal at Glasgow on Dec. 2nd

BY W. S. DUKE-ELDER, M.D., D.Sc. St. And.,
Ph.D. Lond., F.R.C.S. Eng.,
ASSISTANT OPHTHALMIC SURGEON TO ST. GEORGE'S HOSPITAL,
AND ASSISTANT SURGEON TO THE ROYAL LONDON
OPHTHALMIC HOSPITAL.

THE development of any science tends to proceed, not with a regular and even current, but intermittently, like a river which in its placid onward course every now and then bursts into life to hurl itself against the rocks and dash itself pell-mell down a cascade. We get periods of intense creative activity wherein new ideas are developed and new theories are evolved, frequently in bewildering confusion and usually half assimilated; and these are followed by periods of relative quietude wherein these new ideas are consolidated—periods, it is true, less dramatic, but nevertheless as useful, wherein the flotsam can be discarded and that which is good and of permanent value can be gathered, assorted, and stored.

I would like to divide a review of the history of ophthalmology into five such periods as these. The first may be said to have culminated in the middle of last century with the great clinician whose memory we are keeping alive to-day. It is difficult to name this period, but perhaps it may justly be called the age of clinical intuition. It is more difficult to realise the handicaps and disabilities under which these early workers laboured, relying entirely upon the evidence of their senses and the lessons of their experience, without any means of detailed clinical examination, without asepsis and with no anæsthetics, with little or no pathological knowledge, with a meagre physiology and with no biochemistry. But when we realise their difficulties we can only marvel at the clinical acumen and profound insight to which the greatest of them attained, which allowed William McKenzie to establish the fact of sympathetic ophthalmitis, to lay his finger on the essential factor in glaucoma, and to write one of the most extraordinary works on ophthalmology in the whole of the world's literature—his "Treatise on the Diseases of the Eye." The second period was born with the ophthalmoscope, and when the inner eye could be directly observed by means of Helmholtz's instrument, ophthalmology became galvanised into an age of activity the like of which it had never seen before. The third period was the age of the microscope, when with the intensive study of pathology that engaged all the clinics of Europe at the end of last century and the beginning of the present one, our knowledge of the gross anatomy of diseases of the eye increased by *leaps and bounds*; it was a period full of memorable achievements, and it yielded a harvest the value of which will stand for all time. When Gullstrand perfected the slit-lamp some 18 years ago, a fourth era was ushered in, when the study of the pathology of the dead gave way to the study of the pathology of the living. Although it is easy to over-estimate its value, it cannot be denied that the greater facilities with which this new method of examination provided the clinician gave an immense impetus to research, and was responsible, and is still, for a mass of clinical observations which, without its aid, would have remained largely academic and divorced from the routine and practice of the clinic.

But I think it must probably be admitted that while the spirit of clinical inquiry is with us always, the ophthalmoscope has told us most of its secrets, the microscope has pictured most of the mysteries to which histology can reach, and even the slit-lamp, although it has not yet expended all its potentialities, can hardly create a new revolution. Man, in his insatiable quest for more and yet more knowledge, is turning to something else. This brings us to the fifth stage in the history of our subject; and I hope that time will show that I am not over-optimistic when I propose to call it the age of physiology and biochemistry.

A NEW POINT OF VIEW.

We all know of the clinical picture presented to us by McKenzie; we have seen the eye through the ophthalmoscope of Helmholtz, the microscope of Bowman, and the slit-lamp of Gullstrand. I want to put before you a further picture; I am going to ask you to look at ophthalmology with the eyes of a chemist and physiologist. I shall ask you to look upon the eye, not as an organ built up of a few component parts—of three outer tunics and three inner humours—but to look within and beyond this picture to something more fundamental, to lose your accustomed sense of magnitudes, and see an infinitude of molecules and atoms, each inordinately busy travelling in its own appointed path, each running within the limits of certain laws, and controlled by complex but unalterable forces: the whole assemblage partitioned off by membranes through which in certain circumstances they may pass, semi-isolated but coördinated, so that they all together comprise a teeming biochemical factory, complete in itself, but at the same time working in harmony with the larger biochemical factory of the body of which it forms a part.

The most fundamental thing which has occurred in biochemistry in recent times is the establishment by Prof. F. G. Donnan of the laws which govern the passage of dissolved substances through membranes. The whole body is divided up into cells, each separated by membranes from its neighbours, and even within the cell itself there is a complexity of potential membranes. All the active constituents of the body are dissolved in watery solution, and hence it follows that all the activity which takes place, and all the means of communication between the individual cell-units, must necessarily resolve itself into a question of the passage of dissolved substances through membranes. The matter, however, is not so simple as at first sight it may appear, for the membranes, as a rule, allow only the smaller molecules to pass through them and keep the larger ones behind. This provides one means of complication. Moreover, we know that each molecule of salt in solution is broken up into two ions, each of which carries an electric charge—the one a positive charge and the other a negative. Since, therefore, a free diffusion of all ions equally is precluded by the semi-permeability of the membranes, this rearrangement and difference in concentration at once involves the development of hydrostatic, osmotic, and electrostatic forces. Stability and equilibrium can only be reached when all these forces are made to balance, the one compensating for the other. It is the interaction and rearrangement of these forces which is necessary to prevent the occurrence of an explosion, as it were, that constitutes a thermo-dynamical equilibrium.

We will see more clearly what is entailed by this conception when we take a specific instance; but I should like to divide the whole of the vegetative physiology of the eye into four such equilibria: (1) The equilibrium between the blood plasma in the capillaries and the intra-ocular fluid. (2) The equilibrium between the intra-ocular fluids and the vitreous body. (3) The equilibrium between the intra-ocular fluids and the lens. (4) The equilibrium between the blood plasma in the chorio-capillaris and the sensory epithelium of the retina.

THE INTRA-OCULAR FLUID.

We will look first of all at the equilibrium between the blood and the intra-ocular fluid, because this is the most fundamental one. By the intra-ocular fluid I mean not only the aqueous humour but also the fluid in the tissue spaces of the eye, in the uveal tract, in the cornea, and in the retina—all the fluid within the sclerotic, in fact, which is not included within the compass of the other three equilibria.

It is through the membrane formed by the capillary wall that all vital changes associated with the interchange between the blood and the tissues take place. We can picture the mechanism by a scheme like the following, where we will presume, for the sake of simplicity, that the blood possesses two kinds of molecules only: large molecules (protein, such as sodium albuminate), the colloid part of which cannot get through the membrane, and smaller molecules which can. Some of the latter are broken up into particles which are ionised and carry an electric charge (salt), and some which, being non-electrolytes, are not thus broken up (sugar). Now when we try to establish connexion across the membrane, the negatively charged albuminate (A) is held back, and with it, for electrostatic reasons, some of the positively charged sodium ions will be retained also. So far as the diffusible ions are concerned (NaCl) Donnan has shown that, in order to attain a state of equilibrium, they must obey certain conditions by which the products of their concentrations are equal on both sides of the membrane. It follows, since there are more positively charged sodium ions in the blood, that there must be more negatively charged chlorine ions in the aqueous humour. The sugar (S) which, not being ionised and carrying no electric charge, is not subject to those electrostatic constraints, is free to distribute itself equally between two fluids. We have, therefore, a definite and well-defined concentration of the various chemical substances, and this concentration involves specific osmotic and electrostatic forces which combine together to equilibriate each other.

Blood.	*Aqueous.*
A^-	
Na^+	
Na^+	Na^+
Cl^-	Cl^-
S	S

Let us pause for a moment to see how actual facts conform to these theoretical considerations. A thorough analysis of the chemical composition of the aqueous humour[1] shows that it contains all the constituents of the blood plasma. The colloids, however, not readily obtaining a passage through the membrane, are present only in traces; the non-electrolised constitutents are present in equal amounts, and the ionised substances are partitioned exactly in the proportion which the postulates of a thermodynamical equilibrium necessitate. I know of few biological relationships where theoretical values are so exactly attained. For example, I have found that while the sugar in the arterial plasma is 0·158 g. per cent. and in venous 0·133 per cent., that in the aqueous is 0·151 g. per cent., which approximates the value which must of necessity be found in the capillaries. Again, to take an ionised substance, the concentrations of normal sodium in the aqueous and in the blood are as 121 : 145, while those of the chlorine similarly expressed are as 123 : 103. We see that the concentration of negatively charged chlorine in the aqueous is the greater, and the concentration of positively charged sodium in the blood is the greater; and when we take the product of the ions of the two fluids, which theoretically should be equal, we arrive at the figure 148·83 = 149·35—an exceedingly close approximation for any biological estimation.

So much for the chemical equilibrium; let us now turn to the physical one. The osmotic pressure of the aqueous humour[2] exactly corresponds to the very precise value necessitated by the peculiar distribution of ions which we have just considered. The differences in electrical charge imply a difference in electrical potential between the two fluids, and if this is measured galvanometrically by inserting one electrode into the jugular vein and the other into the chamber of the eye, this difference is obtained. Again, the hydrostatic pressures in the eye[3]—the pressure in the entering arteries,[4] in the exit veins,[5] and the pressure in the chambers of the eye—are at exactly the correct level.[16]

Moreover, in abnormal conditions changes take place in the aqueous humour exactly in terms of the some equilibrium.[6] An alteration may be brought about by two conditions: first, by altering the permeability of the capillary walls so as to allow more substances through from the blood; and second, by altering the composition of the blood so that different materials are available to pass through. In the first case if the capillary permeability is increased, as by a dilatation of their walls, a greater amount of colloids will get into the eye and thus an albuminous or plasmoid aqueous is formed. Here, since the electrical strain between the two fluids is now lessened, the concentration of the positive ions increases while that of the negatively charged ions diminishes, the osmotic pressure and the electrical potential fall, the concentration of hydrogen ions rises, and the pressure of the eye increases. This always occurs in such a way that a perfect thermodynamical equilibrium is continually maintained no matter how the alteration in capillary permeability is brought about, whether by processes so divergent as a simple paracentesis or an inflammation of the eye. In the alternative case, if the composition of the blood is altered, the constitution of the aqueous humour alters again according to thermodynamical laws. Large-sized molecules injected into the blood even in abnormal concentration will not find their way into the eye except in traces. Thus dyes like trypan blue or congo red do not enter the aqueous humour, and the difficulty of facilitating the entrance of drugs like the large-moleculed organic preparations of arsenic is thus explained. To a large extent this accounts also for the therapeutic value of a paracentesis, which, by increasing the capillary permeability, allows the more ready passage of substances of this nature. Further, if positively charged cations are added to the blood they enter the eye only with difficulty. The basic dyes, as neutral red, methylene-blue, kresyl blue, fuchsin, and others, as well as metallic ions such as sodium, mercury, or bismuth, come under this category. On the other hand, negatively charged anions enter readily, dyes like eosin, chrysolin, orange G. and anions such as iodides, chlorides, bromides, and organic anoidal substances such as salicylic acid. It is evident that what used to be called the "selective permeability" of the ciliary epithelium, and which used to be cited as evidence of its secretory activity, is a purely physical process determined by thermodynamical laws.

On either side of the capillary walls there is, therefore, a balancing thermodynamical equilibrium comprised of complex but well-determined chemical, hydrostatic, osmotic, and electrostatic forces. Around this level the mutual compensating forces are continually fluctuating, and in any capillary they will determine a flow of fluid outwards at one moment and inwards at another, accompanied by a diffusion outwards or inwards of diffusible substances according to their several differences in concentration and determined by the nature of their electric charge, while the whole is subject to a readjustment depending on the colloid impermeabilities. This fluid percolates through all the structures within the sclerotic, through the stroma and the cellular elements of the ocular tissues, through the substance of the cornea, and eventually through the endothelium and epithelium lining the anterior and posterior chambers, filling up these cavities.[7] Throughout its passage across it is modified by metabolic activity and by the stresses to which it is exposed; at all points in its course, between each cell and between the interfaces within each cell, fresh membranes or potential membranes have to be traversed, each involving a new system of forces with the corresponding adjustments which these entail, and each necessitating a fresh state of thermodynamical equilibrium. While this reciprocal interchange occurs throughout all the tissues of the eye, circulatory conditions to a less extent, and the influence of muscular activity to a greater extent, will determine a slow through-and-through circulation of fluid through the chambers of the eye, which will find its exit mainly by way of the canal of Schlemm[8]; while differences of temperature within the anterior chamber itself determines an internal thermal circulation.[6]

THE VITREOUS BODY.

So much for the first equilibrium; we are now in a position to deal more rapidly with the others. The chemical examination of the vitreous body[9] shows that it is made up of all the constituents of the aqueous humour in corresponding proportions with the addition of two specific colloid constituents of ectodermal origin: a mucoprotein and a second protein substance the exact chemical nature of which I have not yet been able to elucidate, and which I am, therefore, in the meantime calling a "residual protein." Each of those two substances has a special function, that of the mucoprotein being the maintenance of transparency, and that of the residual protein the potentiality of gelability. The ultra-microscopic examination of the vitreous body[9] and a study of its physical properties demonstrate beyond doubt that it is, in a fresh and healthy state, a simple and homogeneous jelly or gel; that the fibrillar appearances seen histologically by the microscope are artifacts of coagulation, and the membranous appearances seen clinically by the slit-lamp are similarly optical artifacts. A study of its vapour pressure isotherm[10] shows that it is an elastic turgescible gel, capable of swelling and shrinking. Further, a study of its various reactions shows that, within the limits compatible with life, it tends to swell if the concentration of hydrogen ions is increased, and to shrink if this concentration becomes smaller; while, if its metabolism is upset, the whole gel structure tends to break down, the vitreous body turning fluid and the residual protein material becoming thrown out from its combined state into coagula forming fibres and strands and membranes such as are apparent in the clinical pictures of vitreous opacities with which we are all acquainted.

Here, then, is our second equilibrium. Two special colloid substances are secreted by the surrounding ectoderm, each having a special function of their own; these are percolated by the common intra-ocular fluid which enters into physicochemical combination with them, and the result is the formation of a gel. Always between the two, the intra-ocular fluid and the vitreous body, a continuous thermodynamical equilibrium exists, on the conditions of which depend events like the swelling of the vitreous body, or its shrinkage, or its breakdown into a fluid and the formation in it of opacities; while, superimposed upon this, and dependent to a large extent upon it, is the internal metabolic activity of the vitreous body on the efficiency of which depends its continuance as a homogeneous, solid, and transparent mass.

THE LENS.

The third equilibrium is that between the intra-ocular fluids and the lens. In this case we have some additional stresses in question. The lens to a certain extent forms a separate physicochemical mechanism semi-isolated from the remainder of the eye; its chemical composition is widely different from that of the intra-ocular fluids, to which, indeed, it may be said to bear a relationship showing some points of analogy with the relationship between the red blood corpuscles and the plasma. Corresponding to this, the osmotic pressure of the lens is considerably higher than that of the aqueous by which it is surrounded; it is, in fact, higher by an amount which is approximately equal to a 0·3 normal solution of sodium chloride. Owing to the tonic pull of the capsule through the zonule the internal tension of the lens is kept at a higher level than the remaining tissues of the eye; and therefore it follows that the osmotic tendency for fluid to enter the lens is counterbalanced by the opposing force exercised mechanically by the tension of the capsule favouring the hydrostatic diffusion of fluid out of the lens. Superimposed upon the normal thermodynamical equilibrium, there is therefore a constant expenditure of osmotic work acting against the filtration pressure generated by the ciliary muscle. The effects of the disruption of these forces are seen in their most dramatic form when the hydrostatic component is abolished by a rupture of the continuity of the capsule, and a traumatic cataract is formed. It is seen almost as dramatically when the osmotic balance is disorganised in diabetes when fluid tends to enter the lens.[11] If the process is a mild one the lens swells and is deformed, its curvature and refractive powers are increased, and the acute myopia of diabetes results [15]; if the process is more active, actual droplets of fluid are formed underneath the capsule, and eventually a typical diabetic cataract results. Again, if the efficiency of the membrane is impaired by radiant energy, the abnormal interchange which is thus allowed may, with a direct denaturation of the lens proteins, combine to bring about a radiational cataract.

We have thus a delicately balanced equilibrium between the intra-ocular fluids and the lens on either side of the membrane formed by the lens capsule. The story, however, does not end here. We have here again the same combination of two sets of circumstances as we have seen in the vitreous body. There is first the outer equilibrium, and here again it is to be noted that the two great factors in its derangement which are of greatest importance are an alteration in the concentration of the hydrogen ions and an alteration in the concentration of salts—both of these lead to swellings and shrinkages and disorganisation of the vitreous body, and both of them lead experimentally to the formation of opacities in the lens. The second set of circumstances is the internal metabolism. It has been shown that the metabolism of the lens is subserved by an internal autoxidation system, one of those very interesting and widely occurring mechanisms by which a chemical reaction is maintained in a state of constant and balanced activity, so that a continual reciprocal process of oxidation and reduction is maintained without any mediation of the gases of the blood stream. In this mechanism glutathione acts as a hydrogen donator and β-crystallin acts as a thermostable residue, and it has been shown that an upset of their reversible interaction is a constant accompaniment of the development of cataract. This again is essentially and primarily dependent on the state and the conditions of the outer equilibrium.

THE RETINA.

The fourth equilibrium we can deal with rapidly, not because of its less importance, but, unfortunately, because of our less knowledge of it. The inner cerebral layers of the retina are nourished by dialysation from the retinal vessels just as are the other ocular tissues, with the reservation that, provided as these vascular channels are with insulating perivascular glial sheaths, the cerebral type of circulation is maintained. But the sensory epithelium of the retina receives its nourishment by dialysation through the more distally placed vessels of the chorio-capillaris. Experimental evidence has been brought forward that a local upset of this process produces a derangement of the physico-chemical activity of the precipient elements of the retina such as is apparent clinically as a scotoma. I think it is probable that a disturbance of some such nature as this will eventually be found to account for some of the visual symptoms which may be present in disease. For example, in glaucoma, although the visual symptoms usually run parallel with the major symptom of tension, it cannot be claimed that the parallelism is invariably maintained, and it seems to me not unlikely that, if physico-chemical disturbances in the first two equilibria which we have discussed can give rise to a turgescence of the vitreous, which is evident clinically as a rise of tension, similar or related disturbances in this fourth equilibrium can as easily and as logically put out of gear the still more delicate physico-chemical mechanism which converts radiant energy into nerve impulses in the retina.[18]

CLINICAL APPLICATIONS: GLAUCOMA.

It will be realised that the clinical applications of these physiological considerations are far-reaching. Apart from inflammatory conditions, the pathology of which resembles that of similar conditions occurring in the other organs of the body, almost all of the major diseases of the eye, the treatment of which offers so many baffling problems, resolve themselves into exercises in physico-chemistry. Glaucoma, for example, is not, I think, a condition primarily of raised tension, but is an upset of the entire internal economy of the eye, most usually of a physico-chemical nature, the most frequent and clamantly obvious manifestation of which is an increase in the intra-ocular pressure. The facilities for drainage at the canal of Schlemm are not usually (although they certainly may be sometimes) the primary cause of the trouble; they frequently form the last link in a chain which determines mechanically the final crisis in the disease. There are probably two main factors in the ætiology of this disease, two factors which perhaps determine two types of the disease.[17] Pathologically these two types are evident; the one wherein the uveal vessels are dilated and are surrounded by an abundant exude of fibrinous coagulum; the other where the uveal tract and all the tissues of the eye are compressed and flattened by a swollen vitreous body. The first factor is a derangement of the capillaries, involving a dilatation, an increased permeability, and an upset of the first equilibrium between the intra-ocular fluids and the blood plasma. This may be dependent upon general causes—toxæmic, infective, dietetic, hormonal; it may be related to a derangement of the sympathetic nervous system; or, on the other hand, experimental evidence which we are at present accumulating suggests that it may be to some extent due to the local activity of specific substances in the eye such as choline. The second factor is an upset of the second equilibrium involving physico-chemical changes, such as swelling and turgescence, in the vitreous body. The occurrence of such an upset may depend upon considerations such as the concentration of hydrogen ions [13] or of salts [4] in association with the vitreous body, the inter-relation of its iso-electric points, its oxidative mechanism, or its internal metabolic activity. Certainly the clinical picture seen in many cases of acute glaucoma, and frequently of chronic glaucoma, strongly suggests that a swelling of the vitreous body is of primary importance. The shallow anterior chamber, the obvious pushing forward of the lens and iris, the thinning of the choroid and compression of the retina, combined with the fact that in quite a fair percentage of cases the angle of the iris seems pathologically to be free, points to this conclusion. If a damming back of fluid at the filtration channels were the primary cause, we would look for a deep anterior chamber owing to the retention of the aqueous humour. An obstruction of the filtration passages certainly abolishes the safety-valve mechanism which tends to prevent rises of pressure in the eye by allowing an escape of fluid; but it seems that, in many cases, its part in the ætiology of the disease is that of an adjuvant rather than of a primary factor. It may be that, in most cases, the changes in the vitreous depend primarily upon vascular changes and a derangement of the first equilibrium; while, on the contrary, it is possible that metabolic disturbances in the vitreous itself may secondarily promote the formation of choline-like bodies in the eye which may secondarily produce a vascular crisis in the capillary circulation. Or, even more probably still, the one may aid and abet the other, and a vicious circle may be inaugurated and maintained until the eye itself is strangulated.

Detachment of the Retina.

Again, idiopathic detachment of the retina very probably results directly from changes of the opposite kind, for I think that it is likely that it is preceded and accompanied in the great majority of cases by shrinkage and liquefaction of the vitreous gel. Such a liquefaction can be brought about in the laboratory by simple trauma or by an interference with its normal metabolism, in either of which case the gel breaks down and the residual protein separates out. When this occurs and when liquefaction or shrinkage of the gel takes place, the process is accompanied by a change in the physical state of the comparatively large quantities of water retained by absorption by the colloidal elements of the vitreous; this fluid, being released from its "bound" condition, will once more revert to its original state of "free" intra-ocular fluid. As such it can readily escape from the vitreous chamber, or even leave the eye through the filtration channels at the angle of the anterior chamber in the same way as the rest of the aqueous humour. Any small degree of increased tension in the eye from any cause whatever, no matter how incidental it may be, will involve a loss of some of the intra-ocular fluid through the filtration spaces at the angle of the iris. This is replaced by the exudation of a fluid rich in colloids during the phase of low tension which follows the phase of high tension; any increased capillary permeability arising, for example, from a local inflammatory lesion will lead to the same result, and the fluid thus exuding from the dilated choroidal capillaries will collect more easily underneath the ill-supported retina than any other place. With the retina unsupported by a solid mass, therefore, and deprived of a resilient and steady pressure from within-side, the stage is set and everything is ready for this tissue floating away from its surroundings on the slightest provocation. In this case the essential precursor and primary factor in the ætiology of a detachment of the retina of this nature is a biochemical change in the vitreous body involving a shrinkage of the gel mass and the replacement of part of its volume by free fluid; or, alternatively, a liquefaction of the whole or part of the gel with the formation of a sol containing opacities. It follows that the treatment is ideally by physico-chemical means, by bringing about a solidification and returgescence of the gel which will push the retina by pressure from behind back into place and retain it there.

Vitreous Opacities.

I have shown experimentally that the vitreous body in normal conditions is a gel in a high state of turgescence; as such it possesses an extreme degree of lability. So much is this the case that it can be transformed into a fluid solution by any slight interference with its normal condition. Now this gel-sol transformation is accompanied by the formation of a cloud of minute punctiform opacities and by the separation of the highly gelable residual protein into long films and strands. A similar transformation occurs under the influence of acid or alkaline solutions. In these circumstances the clear mass of gel shrinks up into a small fraction of its original volume; this, of course, is due to a loss of water on a large scale by the individual particles which become deturgesced and occupy a small fraction of their original volume. The fluid thus lost separates out as a clear solution leaving the shrunken gel mass behind. At the same time the gel becomes interspersed by an ever-thickening felt-work of white strands and fibres which alternate with gossamer-like membranes floating about in its interior, and the process goes on until the whole mass becomes turbid and opaque. This behaviour is exactly simulated by a gel of gelatin when it is saturated beyond its solubility limit at its iso-electric point, under which circumstances it turns into an opaque suspension.

We have thus arrived at an explanation, or at any rate at a tentative explanation, of the occurrence of one class of vitreous opacities. We may divide these into two kinds: first, exogenous materials, foreign inflammatory products which are derived from the ciliary body, the choroid, and the retina in cases of cyclitis, choroiditis, and retinitis. The pathology of these is already well understood; they are of the nature of exudates, leucocytes, and other inflammatory products, which may remain unchanged in nature for an indefinite time, or may undergo organisation, or even may assume frankly purulent characteristics. The second class of opacities is autogenous in nature, derived from the vitreous body itself by its partial or complete breakdown. Such a breakdown could readily be brought about clinically by a derangement of the metabolism of the vitreous such as would be caused by low-grade toxins, or by mild inflammatory processes. The strands and diaphanous sheets and membranes seen floating about in a fluid vitreous in a case of chronic cyclitis provide an appearance strikingly similar to that obtained experimentally in the test-tube when the proteins, especially the "residual protein," become coagulated out. Such is almost certainly the nature of the so-called "degeneration" of the vitreous in which the mass turns fluid and becomes filled with opacities which occurs in infective conditions, in senility, in advanced myopia, and which accompanies detachment of the retina.

Cataract.

Cataract, as we have seen, is another purely physico-chemical problem—the denaturation, hydrolysis, and coagulation of the proteins of the lens—and the essential opacities which occur in the cornea seem to be of the same nature. All of these conditions will before long be explicable, and all of them should eventually be curable or preventable by physico-chemical means.

Do not misinterpret me here. So far we can neither cure nor prevent a single one of them. With regard to some of them, it is true, we have got inklings of possible paths which may perchance lead us far along the road, and here and there one or two sign-posts have been erected leading no one knows whither. But on the whole we are merely at the stage of work, and work largely in the dark, relieved only by hopes and aspirations; and not within the lifetime of any of us will all of these hopes and aspirations be realised. I am merely trying to suggest a new point of view. In the past we have been looking at the diseases of the eye almost entirely from the viewpoint of anatomical pathology—a most useful and, indeed, a necessary stage in the evolution of knowledge. But hitherto we have tended to make too much, I think, of the structural ruins which disease has left behind it, and we have failed to see the deeper and more subtle nature of the initial defect.

Again, do not misinterpret me by crediting me with the suggestion that with the knowledge of physico-chemistry which we possess or which we can ever hope to possess, we will ever be able to penetrate fully into the processes of life and disease. It is true, I am convinced, that the body is a physico-chemical mechanism, and that consequently a physico-chemical method is the only one which can legitimately and rationally hope to elucidate its activities. But still more certainly we know that the chemistry or the physics at our command does no more than touch the fringe of the universe of natural phenomena. It would be dangerous to delude ourselves that there is any physiological process at all, with its multiplicity of parallel reactions, interdependent, inter-related, and interwoven, which is as yet so susceptible to simplification that it can be accounted for by a definitive explanation along these lines. At the same time I see no reason to despair that eventually the instability and plasticity of the physico-chemical structure of protoplasm may permit of an adequate and pragmatic explanation, and it seems reasonable to hope that in the future its ceaseless evolution, its histogenic powers, and its teleological attributes may to some extent, at any rate, be clarified. But even if it does finally become apparent that knowledge in its progress will never reach this goal, but, "like curves of the geometrician, will always approach but never attain its asymptote," we, in our own time, can share the spirit of adventure of the voyager who sails one stage further out upon the uncharted sea. And if we, as a generation witnessing these researches after truth, sharing in them, and doing our part to help them along, add even one small quota to the sum of experience and hand it on to our intellectual heirs, we, as a generation, may have it haply said about us that we picked up the mantle so grandly worn by McKenzie, and have done our best to carry it gallantly and well.

TREATMENT OF PERFORATED PEPTIC ULCER.

BY HERBERT WILLIAMS, M.B., F.R.C.S. EDIN., F.R.C.S. ENG.,

HON. SURGEON, ROYAL SOUTHERN HOSPITAL, LIVERPOOL; VISITING SURGEON, MILL ROAD INFIRMARY, LIVERPOOL; LECTURER ON CLINICAL SURGERY, UNIVERSITY OF LIVERPOOL;

AND

CHARLES H. WALSH, M.B., D.P.H. LIVERP.,

LATE SENIOR SURGICAL OFFICER, MILL ROAD INFIRMARY; VISITING GYNÆCOLOGIST TO THE INFIRMARY.

MUCH has been written in recent years on the treatment of perforated peptic ulcers of the stomach and duodenum, and it is surprising how much opinion differs about the best surgical procedure. Some surgeons favour primary gastro-jejunostomy as a routine, whilst others never carry this out at the primary operation. Guthrie[1] sent a questionaire to 149 surgeons in America to ascertain their practice, and found that 22 performed primary gastro-jejunostomy as a routine, 64 never performed primary gastro-jejunostomy, and 63 performed primary gastro-jejunostomy in a shifting percentage depending on the condition of the patient. In view of these differences in practice it may be of interest to record the results of 158 cases of perforation of the stomach and duodenum operated upon in one hospital by several operators[*] in the last seven years, all using the same technique.

Briefly, our practice has been to operate upon all cases without selection—to close the perforation, to drain the peritoneal cavity, never to do primary gastro-jejunostomy, and to complete the operation with all speed.

Age Incidence.[†]—Perforation is uncommon in patients under 25 years and over 60 years of age. It occurs most frequently in the fourth and fifth decade but it is quite common in the sixth. Table I. shows the number of cases in each decade.

Sex Incidence.—In this series 152 were males and 6 were females, a proportion of 25 to 1. Two of the female cases were duodenal perforations and the remaining four were gastric.

Site of Perforation.—In our experience duodenal perforation is more frequent than gastric perforation. Of the 158 cases, 124 were duodenal and 34 gastric, giving a proportion of approximately four duodenal and one gastric. In no cases have we found more than one perforation at the time of operation. Recurrence of perforation at the same site has occurred in three cases: in one after an interval of 11 months, in another after four years, and in the remaining case after five years. In two of these cases no gastro-jejunostomy had been performed; in the third gastro-jejunostomy was performed but was undone at a later date for jejunal ulceration. Two years after the normal anatomy of the stomach had been restored perforation occurred again. Sometimes there is difficulty in deciding the exact site of the perforation in juxtapyloric cases, and our method of discrimination is to inspect and to palpate the pylorus carefully. The pyloric vein usually indicates the boundary-line between stomach and duodenum, but we place more reliance on the palpation of the pyloric sphincter by the finger and thumb of one hand to indicate the exact site of the lesion.

TABLE I.

Treatment.

As soon as the diagnosis of perforation is made the patient is placed in the Fowler position and is prepared for operation. His transit from ward to theatre should be performed with the least possible disturbance of this position—that is to say, pillows are placed under the head and shoulders on the ambulance trolley and he is transferred to the operating table already fixed in an inclined position of 20 degrees from the horizontal. We believe that if this position is adopted from the beginning and maintained the bulk of the fluid gravitates to the pelvis by the time of operation, and less swabbing of the upper abdomen is required. Morphia gr. 1/6 and atropine gr. 1/100 are given as routine before operation. The anæsthetic employed in the majority of our cases has been open ether, but latterly we have used gas, oxygen, and ether.

Incision.—A median incision is used, extending from near the xiphoid sternum to the umbilicus. We have found this to give adequate exposure of the perforation in all our cases. The advantages over the paramedian incision are that this incision consumes less time, does not open the rectus sheath, and does not interfere with the use of the paramedian incision for any subsequent operation that may be required.

Closure of the Perforation.—The perforation is immediately sought and the fluid that usually obstructs the view is gently mopped up. The pyloric end of the stomach is held by the finger and thumb of the assistant in such a way as to bring the perforation towards the abdominal incision without exerting any undue traction. If the perforation is pyloric or duodenal, as it most frequently is, the right lip of the incision and the edge of the liver are protected by a swab and retracted. The perforation is closed with a single mattress stitch. Not infrequently, owing to surrounding inflammation, this is not possible, as the stitch cuts through the friable tissue; the surgeon therefore has to proceed to the next stage.

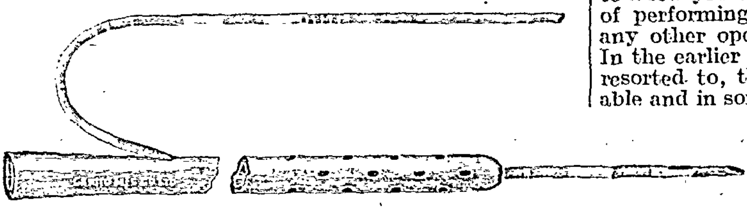
[†] Since this paper has been written, a case of perforated gastric ulcer in a boy aged 16 years has been admitted to hospital. This case is being reported elsewhere by Dr. R. A. M. Pennington.

The ulcer is now infolded by a continuous catgut suture which, in the pyloro-duodenal area, should be transverse to the axis of the bowel and should begin well below and end well above the perforation. We use one seromuscular suture only, as the use of more causes too much invagination and consequent obstruction at the site of the ulcer. When there is much local induration and œdema it may be necessary to go some distance from the perforation to get tissue that will hold the suture. In cases of doubt the suture line is reinforced by stitching over it a piece of the right edge of the great omentum. Where the ulcer is a large one and the surrounding induration and inflammation is extensive the amount of infolding that is necessary to ensure closure of the perforation causes definite obstruction at the pylorus. This is overcome by a special procedure, the double tube technique, that will be described later.

FIG 1.



The double drainage-tube described in the text. (Made by the Genito-Urinary Manufacturing Co., Ltd., London.)

Excision of the Ulcer and Pyloroplasty.—We have done this in nine cases only. It takes extra time, but not so much as is required for a gastro-jejunostomy. It is not suitable for all cases, and can only be carried out with ease where the duodenum is movable. Of 55 consecutive cases in our series 26 have been suitable for excision and pyloroplasty as judged by the mobility of the duodenum and size of the ulcer perforation. When the duodenum is fixed to the posterior abdominal wall the operation is a difficult and dangerous one. Of our nine cases, three died; in one the result was unsatisfactory and in five satisfactory. Rowlands and Turner [2] quote twelve cases of primary pyloroplasty, of which five had recurrence of symptoms.

Cleansing the Peritoneal Sac.

Peritonitis is still the most frequent cause of death after operations for perforated peptic ulcer, and the prevention of this complication is of cardinal importance. While fully appreciating the natural power of the peritoneum to deal with noxious contents, it is easy to err on the side of expecting the peritoneum to do too much. It is argued that a large proportion of the fluid is protective peritoneal exudate. This is undoubtedly true, but at the same time analysis of the fluid shows that a very substantial portion of it is gastric contents, containing partially digested food, gastric secretion, mucus, and bile—all substances very noxious to the peritoneum. If such fluid can be removed by means other than peritoneal absorption it is clearly an advantage to the patient. Further, the infectivity of the fluid must be considered. In this connexion the observations of Bruett [3] in 112 cases are of importance. He reports that in the cases that were operated on from six to twelve hours after perforation the exudate was sterile in only 26 per cent. In cases more than twelve hours old only 7 per cent. had a sterile exudate. Among the bacteria found were staphylococci, *Streptococcus hæmolyticus*, *Streptococcus viridans*, and *Bacillus coli communis*. The type of infection and its virulence must always remain an unknown factor at the time of operation, and obviously the safest procedure is to remove as much as possible of this potential cause of peritonitis.

The ideal method of removing the fluid is one that does not entail manipulation and disturbance of the abdominal contents, and does not traumatise the endothelial covering of the peritoneum. Flushing, which at one time was the common practice, is now almost entirely abandoned. It was ineffective, spread contamination, lowered the blood pressure, and gave very unsatisfactory results. In our earlier cases we used swabbing extensively, but later experience has led us to use it less and less. In 62 of the cases we have at times, varying from a few months to a few years, reopened the abdomen for the purpose of performing a gastro-jejunostomy or carrying out any other operation that may have been indicated. In the earlier cases, where swabbing had been widely resorted to, the peritoneal adhesions were considerable and in some cases extensive. In the later cases, where swabbing has been reduced to a minimum and the chief reliance placed on drainage, the adhesions have been far fewer and in many cases practically absent. We have used suction in several cases but have been disappointed with it. It certainly removes a pelvic collection of fluid very effectively, but that is not all the fluid that is present. There is still a film left between the coils of intestine and mesenteric folds and, though the quantity in any one place is small, the amount in the whole contaminated area of peritoneum is considerable. For the removal of this disseminated contamination suction is ineffective. Moreover, the great omentum behaves almost like fluid and becomes entangled in the nozzle of the aspirator no matter what type of guard is used. Disengaging the omentum causes trauma and waste of time.

We now depend almost entirely on suprapubic drainage and, except in cases where the amount of intraperitoneal fluid is very small, we use drainage as a routine. In this series only three cases were closed without drainage. The insertion of a split tube through a suprapubic stab wound down to the floor of the pelvis and the rigid maintenance of the Fowler position we have found to be the most effective method of coping with peritoneal contamination. The tube is removed at the end of 36 hours. We do not concur with the view that a tube placed in the pelvis does not drain the peritoneal cavity. That such drainage is effective for a period of 24–36 hours is proved by the following observations.

FIG. 2.

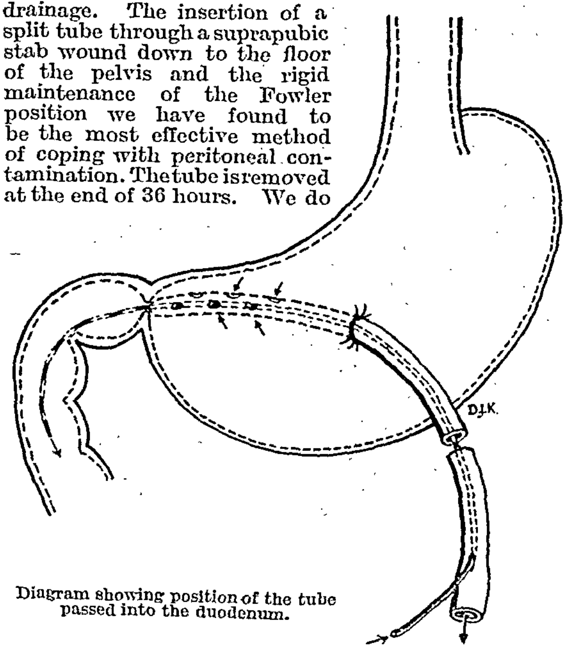


Diagram showing position of the tube passed into the duodenum.

In three successive cases of perforated peptic ulcer, after the tube had been inserted and just before stitching up the epigastric incision, 2 c.cm. of brilliant green was deposited in the peritoneal cavity at the side of the duodenum. The epigastric incision was closed in the usual way. Within a few minutes, and before the patient had left the operating table, the dye made its appearance through the suprapubic tube. The dressing was changed four-hourly, and the amount of staining of the gauze and wool noted. The staining was more intense in the first three dressings, and steadily diminished in intensity up to 24 hours. Between 24 and 30 hours the staining was only faint.

It is evident that, for 36 hours at any rate, the peritoneal fluid percolates into the pelvic cavity, and is forced through the tube by the positive intra-peritoneal pressure. The tube can be rapidly inserted in the following way. As soon as the perforation is closed, a large square swab is folded on itself four times; it is passed in the hollow of the left hand through the epigastric incision and applied to the peritoneum immediately above the symphysis pubis, taking care that there is no loop of intestine between the swab and the abdominal wall. A stab wound is made on to the swab. The hole in the peritoneum should be large enough to grip the tube firmly after it has been inserted. Instead of cutting down on to a swab one of us (C. H. W.) uses the head of a table-spoon on to the convex under surface of which two rings have been brazed to fit the index and middle fingers. The epigastric incision is closed without drainage.

The Double-tube Technique.

Where the ulcer is large and the surrounding induration extensive, the amount of infolding that is necessary to ensure closure of the perforation causes definite obstruction at the pylorus. This difficulty is overcome by means of a double tube (Fig. 1), which serves the dual purpose of draining the stomach promixal to the obstruction and introducing fluid into the duodenum beyond the obstruction. It is in effect a gastrostomy and an enterostomy. The outer tube is made of rubber similar to an ordinary catheter of about 22 Charrière. It is perforated with several holes for a distance of one and a half inches from the tip. There is a further oblique perforation at the side of the tube near the flange and a terminal one at the tip. This latter perforation is just large enough to admit a No. 8 ureteric catheter. The inner tube consists of a ureteric catheter, which is passed into the outer tube through the side hole near the flange and out through the terminal opening. The tip of the inner tube at the time of introduction should just present at the tip of the outer tube. The double tube is introduced through a small incision in the anterior wall of the stomach at a point about three inches from the pylorus. It is passed with the right hand and guided by palpation through the stomach wall with the left hand. When the outer tube abuts on the gastric side of the obstruction, the inner tube is pushed through the stenosis and guided on until its tip lies in the second part of the duodenum (Fig. 2). The perforated part of the outer tube thus lies in the pyloric part of the stomach and proximal to the obstruction. It is now fixed in the wall of the stomach after Stamm's method and brought out through the epigastric incision without kinking (Fig. 3).

The outer tube allows gas to escape, and any gastric contents that may come away are led into a bottle attached to the patient's dressing. The inner tube is used for introducing fluid into the duodenum by means of a record syringe, the needle of which is passed into the proximal end of this tube. Our practice is to give 40 c.cm. of glucose solution every half hour for the first twelve hours and then to diminish the quantity according to the needs of the patient. When not in use the tube is coiled up and fixed to the outside of the dressing with a safety-pin. The inner tube has usually served its purpose by the third day and can be removed, and the outer tube can be taken away any time after the sixth day.

The advantages of this procedure are obvious. 1. It provides a simple and effective way of administering much-needed fluid. 2. It drains the stomach and allows the escape of flatus, thus preventing the very distressing symptoms of gastric distension such as hiccough, nausea, and vomiting.

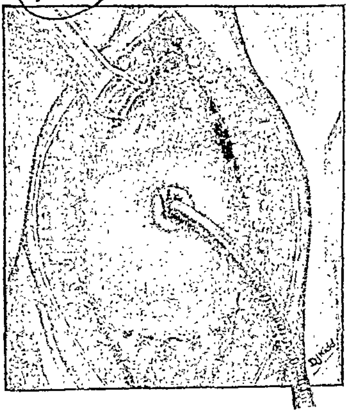
E. R. Schmidt[4] performs gastrostomy as a routine in all cases of perforation. We have not done this in any of our cases, but can testify to the amazingly smooth recovery of the cases in which we have employed gastric drainage as above described.

Gastro-jejunostomy at the Time of Suture.

On no aspect of the treatment of perforated peptic ulcer has there been more controversy than on the question of performing primary gastro-jejunostomy.

231

FIG. 3.



The tube emerging from the wall of the stomach.

Unfortunately, the statistics of the advocates of suture and gastro-jejunostomy are not comparable with those of surgeons who advise suture only. Gastro-jejunostomy is generally carried out in selected cases only, and the statistics of a series of such cases are therefore not comparable with a series when suture only has been done, for the latter would include the bad as well as the good operation risks. In many of our cases where, from the general condition of the patient and the duration and size of the perforation, the case would have been judged fit to withstand a gastro-jejunostomy, we have been impressed with the critical condition they have passed through (not accounted for by pyloric obstruction due to suture) before convalescence is established. We cannot but feel that in many of these cases the additional strain of a gastro-jejunostomy would have turned the scales against them.

More convincing than this clinical impression as to the inexpedience of primary gastro-jejunostomy is the evidence that it is not required in a large proportion of cases. C. E. Gibson[5] reports that only seven out of twenty-eight cases of perforated duodenal ulcer and one out of twenty-eight cases of perforated gastric ulcer required a second operation after suture alone had been carried out. E. H. Pool[6] writes that only one-third of the cases of simple suture develop later symptoms.

Mr. P. H. Mitchiner, of St. Thomas's Hospital, London, in a personal communication, gives figures of 69 cases operated on by him up to 1928. All of them were treated by simple suture without gastro-jejunostomy. In six only was there recurrence of symptoms requiring treatment by operation.

Our figures on this point are complicated by the fact that during the years 1923–26 we carried out delayed gastro-jejunostomy on all cases from six to eight weeks after simple suture. We felt then that an ulcer that was active enough to perforate was sufficient indication for a gastro-jejunostomy. After following this practice for four years we began to realise that in a considerable number of the cases the duodenum and pyloric canal had made such perfect recovery and showed so little deviation from the normal that gastro-jejunostomy seemed unwarranted. We therefore abandoned this practice and now perform secondary operation in those cases only where, after a period of observation, the indications are clear. Of 58 cases managed on these lines we have had to perform secondary operations in ten, but as these are our most recent cases it is probable that this figure will have to be increased. In the main, the cases that are deemed fit for primary gastro-jejunostomy are those with small perforations and slight pathological changes in the adjacent tissues; these are the very cases that will not require it. On the other hand, there is a fair proportion of cases in which the perforation in the neighbourhood of the pylorus is so large and the surrounding induration and fibrosis so extensive that the perforation can only be closed with deep infolding. Immediate or remote stenosis is almost inevitable; these are the cases in which primary gastro-jejunostomy is most strongly indicated, but unfortunately they are the more serious cases and the ones that are least able to withstand the additional strain. The immediate ill-effects of pyloric obstruction can be avoided by adopting the double-tube technique described above. At a later date—any time after six weeks—a gastro-jejunostomy can be performed without appreciably increasing the death-rate. We have carried out delayed gastro-jejunostomy in 56 cases with one death, which was due to broncho-pneumonia. In operating on a case of perforation one should have no thought for the remote result. The immediate object is to save life. These cases are always ones of grave emergency and ones in which the immediate prognosis must be guarded. The additional strain of a gastro-jejunostomy, however dexterously it may be performed, is not justified. The remote result can always be improved by a clearly indicated subsequent operation.

Results.

The more obvious factors concerned in the mortality are the duration, the site, and the size of the perforation. It is noteworthy that we could not trace any relationship between the age of the patient and the prognosis (Table II.). The older patients seem to do almost as well as the young. There are, however, other factors, the importance of which cannot be estimated at the time; the most important of these is the toxicity and type of infection of the intraperitoneal fluid. In our experience perforations of gastric ulcers are more fatal than duodenal perforations. This is due to the facts that gastric ulcer patients are in a lower state of health and the perforations are usually of larger size, with the result that there is more extensive flooding of the peritoneal cavity with toxic material. Furthermore, in five of the thirty-four gastric perforations the underlying condition was carcinoma. Table III. shows the immediate mortality in these cases of perforated gastric ulcer. It is arranged in groups of six-hourly periods, depending on the interval between perforation and operation.

TABLE II.

Age in Q. G.	Total cases.	Duodenal.	Deaths.	Gastric.	Deaths.	Age in Q. G.	Total cases.	Duodenal.	Deaths.	Gastric.	Deaths.
Under 20	1	1	0	0	0	50–54	20	16	5	4	2
20–24	10	8	2	2	1	55–59	11	6	1	5	3
25–29	22	20	5	2	1	60–64	5	2	1	3	2
30–34	19	15	3	4	2	65–69	5	4	3	1	1
35–39	22	20	2	2	2						
40–44	20	15	0	5	3	—	158	124	26	34	21
45–49	23	17	4	6	4						

The immediate cause of death in the twenty fatal cases was as follows:—

Shock of perforation and operation	7
General peritonitis and paralytic ileus	8
Broncho-pneumonia	1
Subphrenic abscess	1
Hæmorrhage	1
Empyema	1
Intestinal obstruction	1

The subsequent history of the 14 recoveries is as follows:—

3 have not required any further operative treatment.
3 have required posterior gastro-jejunostomy.
2 have required partial gastrectomy.

These eight cases have been examined recently and are completely satisfactory.

The remaining six cases have died from diseases as follows:—

2 from cancerous cachexia.
1 from myocardial degeneration.
1 from chronic interstitial nephritis.
1 from empyema following acute lobar pneumonia.
1 from broncho-pneumonia following operation for ventral hernia.

Table IV. shows the immediate mortality in 124 cases of perforated duodenal ulcer. It is arranged as in the gastric cases.

TABLE III.

Hours of perforation.	Total cases.	Recoveries.	Deaths.	Mortality per cent.
0– 6	12	8	4	33·3
6–12	12	6	6	50
12 +	10	—	10	100
—	34	14	20	59

TABLE IV.

Hours of perforation.	Total cases.	Recoveries.	Deaths.	Mortality per cent.
0– 6	67	60	7	10·4
6–12	39	30	9	23
12–18	8	4	4	50
18 +	10	4	6	60
—	124	98	26	20·96

The immediate cause of death in the 26 cases has been:—

General peritonitis and paralytic ileus	16
Shock of perforation and operation	3
Broncho-pneumonia	7

The subsequent history of the 98 cases has been as follows:—

41 have remained satisfactory without further operation.
53 have had posterior gastro-jejunostomy, of which 51 are satisfactory: the other two developed jejunal ulcers and required further surgical measures.

The above 94 cases have been examined recently and we have classified them as satisfactory on these grounds. The patient has a good appetite; has no pain and no vomiting; has little or no flatulence; his weight is stationary or has increased; bowels are regular; scars are healthy; general condition is good; and the patient is able to follow his usual occupation.

Four cases have died subsequently from diseases as follows:—

1 from an accident causing fractured base of the skull.
2 from pulmonary tuberculosis.
1 from broncho-pneumonia following posterior gastro-enterostomy.

Our thanks are due to Dr. R. T. Bailey, medical superintendent, Mill Road Infirmary, Liverpool, for the facilities he has afforded us in carrying out these investigations; also to Sisters L. Handley and E. Irving for the painstaking and efficient way in which they have helped us to follow up the cases.

PARATHYROID TETANY AND CATARACT.

BY LESLIE COLE, M.D. CAMB., M.R.C.P. LOND.,
ASSISTANT PHYSICIAN TO ADDENBROOKE'S HOSPITAL, CAMBRIDGE.

THE association of cataract and muscular spasms has long been recognised, but only gradually have their connexion with an underlying parathyroid deficiency been shown. The results of extirpation of the parathyroids in animals and man have proved the constancy of this syndrome.

In 1906 Erdheim,[1] after removal of the parathyroid glands in rats, observed the onset of tetany, followed six months later by cataract. Hayano[2] also studied the eyes of young parathyroidectomised rats, and in almost all cases observed the appearance of lenticular opacities within a few days of operation. In 1915 Edmunds[3] described the development of cataracts in a parathyroidectomised dog. The animal had been kept alive for two years after operation, tetany being controlled by milk and intravenous calcium injections. The cataracts developed after 23 months. This was confirmed by Dragstedt, Sudan, and Phillips,[4] who discovered *cataracts in six parathyroidectomised* dogs in whom tetany was being controlled by doses of calcium lactate. These cataracts developed in from three to six *months after operation, and pro*gressed in some cases to complete opacity.

In human beings a number of cases of this combination following thyroidectomy have been described. In a review of the recorded cases in 1928, Jacques[5] has collected 31 cases from the German literature, one English case, and described two more. Others have been described by Sainton and Peron,[6] Aub,[7] and Hunter.[8] The following is an account of a further case.

History.

A married woman, aged 34, with three healthy children, first attended out-patients at Addenbrooke's Hospital on March 23rd, 1929. She complained of fits, tingling in the backs of the hands and in the feet, and attacks of dimness of vision.

One sister, aged 14, has a goitre, which was first noticed at the age of 12. One brother died of pulmonary tuberculosis.

History of Present Illness.—The patient was born in Norfolk, and lived there until she was 18. After this she spent periods in Buckinghamshire and Yorkshire, but for the last few years she had lived near Cambridge. At the age of 18 she first noticed a goitre. At 19 she had an operation for removal of glands from the side of her neck. The goitre gradually increased in size, and at the end of 1927 began to cause her great discomfort from pressure. This was especially marked when she lay down, and she then felt she was being choked.

In February, 1928, the pressure symptoms became so severe that partial thyroidectomy was performed. At the operation both lateral lobes of the thyroid gland appear to have been completely removed, while the middle lobe was left. Sections of the excised thyroid showed normal thyroid tissue. The vesicles were distended with colloid, but there was no evidence of hyperplasia.

Within a week of operation she found she could not use her hands properly on account of stiffness of the fingers. When she was drinking a cup of tea her hand would stop in the position in which the cup was held, and would sometimes remain fixed thus for ten minutes. The backs of the hands were intermittently tingling as if they were very cold; when, however, she put them into hot water this became worse. This sensation extended up as far as the middle of the forearm. The elbows were not affected. At the same time there was tingling of the same nature in the feet, but this was less marked, and *the feet did not at that time become fixed.* When the tingling sensation came on in the hands and feet and the hands became fixed the corners of the mouth seemed to be pulled sideways. The tongue "seemed to be cramped," so that she could only use it with difficulty to speak or eat, and swallowing was very difficult. The eyes or voice were not affected at that time.

These symptoms persisted with varying intensity until July, 1928. She was always unable to do any fine work such as knitting or writing, although she could do both these things well before operation. At times she had great difficulty in feeding herself because of the tendency of the hands to become fixed "because they used to go cramped the way I was holding anything." Within a few weeks of the operation cramp came on in the feet, and they used to become fixed in the position in which they were put for ten minutes. The toes were generally drawn downwards and plantar-flexed. This was never sufficiently severe to prevent her walking. At this time the eyesight was not affected, but on extreme deviation of the eyes to the right or left she sometimes had difficulty in bringing them back into the midline position.

In July, 1928, she had a fit. This came on suddenly, without any warning, in the shape of tingling or cramp in the hands or feet. She lost consciousness completely, and did not come round again for over an hour. Her husband described her as very blue during the early part of the fit, and foaming at the mouth. Spasms affected the hands and feet particularly. After this fit she could not see properly after she regained consciousness for almost an hour on account of a mist in front of her eyes. This dimness of vision then passed off completely. In July she had two other similar fits, in one of which she was unconscious for three hours. Each fit was followed by dimness of vision, which passed off after a few hours. She had no more fits after July until the following December. Then she began to have fits daily, at first in the morning when she woke up, but later she had two or three every day, and was liable to them at all times of the day. These continued until March 16th, 1929, and then stopped. In the intervals between the fits tingling of the backs of the hands, stiffness of the wrists and fingers, with complete inability to knit or sew or perform fine movements, *stiffness of the tongue,* and *tingling* and stiffness of the feet continued, sometimes worse, sometimes better. She could not associate the times of exacerbation and remission with any change in her diet or mode of life.

After the first few fits in December the mistiness of vision did not pass off so quickly, and gradually it became continuous, although worse after each fit. Between March 16th and 23rd she had no fits, but the other symptoms continued. Her eyesight did not improve.

Before her operation her periods had always been quite regular. Afterwards they were often irregular as regards time by a week, but were more scanty than before. In November, 1928, she had a miscarriage at two months. From November to March the periods became quite regular again.

On March 23rd she first attended out-patients at Addenbrooke's Hospital. Chvostek's sign was then very pronounced. Percussion over the various branches of the facial nerve at their outlet from the stylomastoid foramen caused twitching of the frontalis muscle as far as the middle of the forehead, of the muscles round the eye, the cheek, round the mouth, and between the corner of the mouth and the point of the chin. Trousseau's sign could not be obtained. She could see well enough to recognise people, and could read ¾ inch headlines with each eye from a distance of a few inches. The serum calcium was found to be 3·2 mm. per 100 c.cm. Accordingly she was ordered a pint and a half of milk and two eggs daily, and given calcium lactate 3 drachms daily.

On April 4th she was admitted as an in-patient. After three days on the above régime her tetanic symptoms became very slight, and she was left with only an occasional tingling feeling in the back of the hands. Her eyesight, however, grew rapidly worse, and on the day of admission she complained that she was almost completely blind.

Physical Signs.

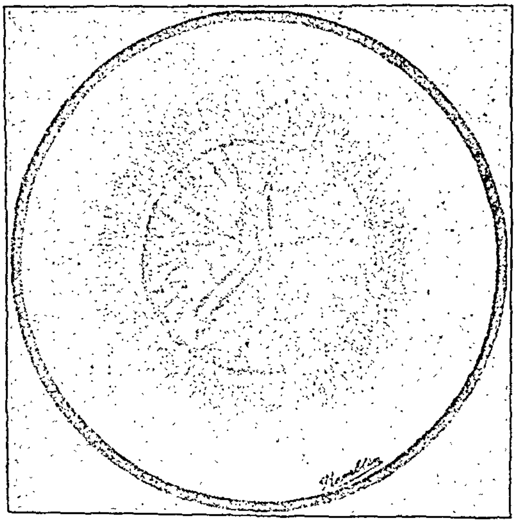
The patient was a robust, healthy-looking woman, with a slow placid manner. Height, 5 ft. 6 in.; weight, 9 st. 1 lb. Intelligence and memory good. Mucous membranes normal in appearance. Hair normal in all parts of the body. Skin normal. Finger- and toe-nails normal. Calcification of the teeth apparently rather above the average, and no caries present (Mr. H. Curtis). The larynx showed no abnormality. Voice and hearing normal. No abnormality found in the central nervous system.

Eyes.—Discs could not be seen on account of the cataract. The patient complained of a white mist in front of the eyes, and both right and left eye could detect movement of the hand at one foot. On examination with the slit-lamp Mr. Arthur Cooke reported: "Both lenses show fairly generalised *cataract*, both central and nuclear, laid down in large pyramidal masses, with bases towards the periphery. These are of no great density, but enough to obscure the red reflex without obliterating it entirely." (See Fig. 1.)

In the *neck* the incisions for thyroidectomy had left an extensive collar scar 6 in. long. A mass of thyroid tissue the size of a golf ball was palpable directly in front of the trachea. No remnants of the lateral lobes could be palpated.

Chvostek's sign was positive. Light percussion over the branches of the facial nerve below the ear caused twitching of the corners of the mouth. The twitching of other parts of the face observed in out-patients ten days before had disappeared. Trousseau's sign was completely negative. Inflation of a sphygmomanometer bag around the upper arm for a period of five minutes produced no abnormal sensations or spasm of hand.

FIG. 1.



Slit-lamp drawing of cataract in the left eye. The changes in the right eye were of equal intensity.

Examination of the heart, lungs, abdomen, and urine was negative. The blood pressure was 115/75, and there was no arterial thickenings or tortuosity.

Other examinations gave the following results:—

Galactose tolerance test: Within normal limits.
Renal efficiency tests: Kidneys efficient.
Wassermann reaction: Negative.
Basal metabolic rate: −2·5 per cent.
Carbon dioxide combining power of the blood: 62 c.cm. per 100 c.cm. serum.
Serum calcium*: 6·2 mg.
Inorganic phosphate in serum (April 9th), 6·9 mg.

Controlled X rays showed no evidence of abnormal calcification in the bones or teeth.

Progress of the Case.

The effects of treatment with parathyroid extract and calcium are shown diagrammatically in Fig. 2. When it was desired to give a calcium-rich diet two pints of milk and two eggs were given, with additional calcium lactate daily. When it was desired to give a calcium-low diet milk and eggs were withdrawn, and the calcium lactate stopped. Collip's[9] parathormone was given by intramuscular injection in doses of 10, 20, or 30 units twice a day, and for one period this was replaced by a well-known brand of dried parathyroid extract by the mouth in doses of gr. 1/5 t.d.s. (equivalent to grs. 6 of the fresh gland per day).

An attempt is also made in Fig. 2 to show the correlation between the intensity of Chvostek's sign with the changes in the blood and the parathyroid and calcium dosage. It was found to be easy to differentiate three definite degrees of intensity of twitch which are represented as follows:—

0. Base line: No twitch at all.
1. Twitching at the angle of the mouth only.
2. Twitching at the angle of the mouth and the outer canthus of the eye.
3. Twitching also of the muscles between the angle of the mouth and the point of the chin, of the muscles of the cheek between the mouth and the eye, of the muscles round the eye, and of the muscles above the eyebrow as far forward as the midline of the forehead.

In this case the relationship between the degree of twitch and the serum calcium seemed to be approximately as follows:—

Serum calcium below 5 mg. per 100 c.cm.: third degree of twitch.
Between 5 and 7 mg.: second degree.
Between 7 and 9 mg.: first degree.
Above 9 mg.: Chvostek's sign negative.
Trousseau's sign was always negative.

With one exception the only symptoms, apart from blindness complained of during treatment, were tingling of the backs of the hands, and, to a lesser extent, of the feet, and stiffness of the fingers. These symptoms only persisted for three days at the commencement of the high calcium diet from April 25th to 28th (the serum calcium on the 28th was 3·2 mg.), and did not return again until the serum calcium fell to below 5 mg., when they appeared for a few days intermittently. For the remainder of the time they were absent.

The one exception was on the day following the day on which the left cataract was needled. Following the operation the patient felt sick and was unable to take any food or calcium lactate. After 24 hours she developed a typical attack of tetany, with hands fixed in the accoucheur position. The feet also were affected to a slighter degree. Calcium lactate was then given by the mouth, and the spasm and tingling gradually passed off. This was the only occasion while she was under observation in hospital on which both parathyroid and calcium were omitted at the same time, and also the only occasion on which she developed true tetany.

After 13 weeks in hospital this patient returned home. She is at present taking 12 drachms of calcium lactate daily, with two pints of milk and two eggs and no parathormone. On this her serum calcium keeps between 5 and 8 mg., she gets occasional attacks of numbness in the hands and feet, but since discharge has had no actual attack of tetany. Chvostek's sign is positive to the first or second degree. The cataracts are being treated surgically by Mr. Arthur Cooke.

Discussion.

An analysis of the 38 recorded cases shows that the results of partial or complete removal of the parathyroid glands may for convenience be divided into two categories: (1) alterations in the calcium and phosphate content of the serum associated with signs and symptoms of tetany; (2) changes in the lenses, nails, teeth, and hair.

Tetany.—In the present case the correlation between the serum calcium and the various manifestations of tetany are again clearly shown. Bauer and Ropes[11] have emphasised the value of calcium lactate ingestion alone in raising the serum calcium in normal subjects. In this case a high calcium diet and calcium lactate, although they had a marked effect in raising the serum calcium and controlling tetany, would not bring it to its usual level unless combined with Collip's parathormone.

In view of the claims for dried parathyroid extract given by the mouth, the effects in this case are interesting:—

Parathormone and a high calcium diet raised the serum calcium from 6·2 to 9·2 mg. in five days, causing Chvostek's sign to disappear, and maintained the calcium at about that level for the next week (dose 20, rising to 40 units daily). The dried parathyroid extract (gr. 1/5 t.d.s.), given for ten days with the identical calcium diet, was associated with a fall in the serum calcium from 6 mg. to 4·6 mg., a return of Chvostek's sign to the third degree, and a return of slight symptoms of tetany.

The clinical manifestations of tetany in this case are typical, except in one particular. Trousseau's sign was always negative, however low the serum calcium and however marked the other symptoms and signs of tetany. Inflation of the sphygmomanometer bag around the upper arm for five minutes did not cause the slightest tendency to spasm in the fingers on any occasion.

---

* All serum calcium and phosphate estimations were done twice and the technique was controlled by frequent estimations on normal serum.

A clinical feature of special interest in Aub's case was the association of asthma and tetany. This patient had had two operations for moderately severe exophthalmic goitre in 1917, and for several years after this had severe attacks of asthma and tetany. These continued until treatment with Collip's parathormone raised the serum calcium to 7 mg., when both asthma and tetany ceased.

The significance of changes in the serum phosphates in parathyroid tetany are not well understood. Gates and Grant,[12] working with parathyroidectomised rabbits, found that a rise in the inorganic phosphorus occurred in some rabbits which did not develop tetany but that it was never absent in those that did, and was apparently associated with the onset of an acute attack. The average Ca/P. (calcium to phosphorus) ratio in normal rabbits was 1·9. In those animals that developed acute tetany after parathyroidectomy this ratio was changed, not only by a fall in the serum calcium, but also by a rise in the phosphates, so that the ratio was then usually below unity. Greenwald[13] has stated that in over 50 parathyroidectomised dogs tetany never appeared without phosphorus retention, and conversely a drop in phosphorus excretion was only observed in one dog in ten that did not develop tetany. Salvesen[14] found that the inorganic phosphorus of the blood-serum of completely parathyroidectomised dogs was considerably increased and tended to remain above the normal value. Salvesen, Hastings, and McIntosh[15] conclude that a fall in blood calcium is the significant factor in the development of tetany. In human beings with parathyroid tetany most recorded readings of the blood phosphates are slightly above normal. This is so in the present case. Variations in the serum phosphates, however, do not appear in this case to have any very close relationship to the degree of excitability of the muscles, whereas the relationship between the serum calcium readings and the intensity of tetanic manifestations is very close indeed. Albright and Ellsworth[16] have lately published some investigations on a case of idiopathic hypoparathyroidism in a boy of 14. They base their diagnosis on the following criteria: low serum calcium, high serum phosphorus, cataract, normal density of the bones by X ray and tetany aggravated by exertion. In this case the injection of Collip's parathormone in a dose of 50 units daily for four days caused an immediate increase in phosphorus excretion, reaching its maximum within two hours, an increase in the serum calcium, an increase in calcium excretion, and a decrease in the serum phosphorus. They bring forward evidence to show that the three latter effects are sequelæ of the increased phosphorus excretion caused in some way by parathyroid hormone.

FIG. 2.

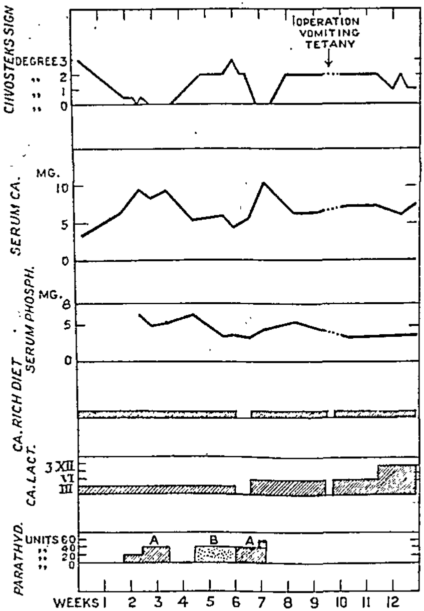


Chart showing variations in Chvostek's sign, serum calcium and serum phosphates during treatment with a calcium-rich diet, calcium lactate, and two kinds of parathyroid extract (A and B). A = Collip. B = Dried extract by mouth.

Changes in the lenses, nails, teeth, and hair.—In an analysis of the 34 cases of cataract after thyroidectomy quoted by Jacques and the four additional cases referred to here, changes of the hair and nails were present in eight and changes of the hair only in three more. In the case described by Sainton and Peron, during the two years following operation, the hair and nails fell out, and the teeth decayed rapidly.

> Two years after operation the patient was bald but for a few dozen dry brittle hairs, and was obliged to wear a wig. The nails were extremely brittle, the tint of old ivory in colour, and the normal striation was accentuated. These changes were accompanied by typical severe attacks of tetany and the development of bilateral cataracts. The authors comment on the fact that their patient showed no sign of myxœdema, although the greater part of the thyroid gland had been removed at operation. One year later the hair had grown again and the nails had become normal in appearance without any systematic treatment.

Jacques, in one of his cases, also describes a similar condition. About three months after operation a rapidly developing alopecia came on and the nails became friable. The teeth, however, showed no abnormality. On large doses of calcium lactate the hair grew again and the slight nail changes disappeared. This patient also showed no signs of myxœdema and the basal metabolic rate was + 3 per cent.

No satisfactory explanation has yet been put forward to account for these changes, and in the absence of more complete knowledge discussion is idle. One fact, however, is worth noticing in the present case, and that was the very rapid increase in the lens opacity which followed an increased calcium diet without parathormone. In two weeks vision practically disappeared in both eyes, while at the same time the tetanic symptoms disappeared. This observation would appear to support Greenwald's[17] evidence that in the absence of the parathyroid hormone there is an extensive deposit of calcium, probably in the form of calcium phosphate, in the tissues, and that the cataracts observed after parathyroidectomy may be due to a deposition of this salt in the lens. As a precautionary measure it seems to be unwise in severe parathyroid tetany, before cataracts have developed, to give an increased calcium diet without parathormone.

There appears to be no equality of effect in the structures affected. For example, in this case, although the serum calcium was extremely low and the tetany and cataracts very severe, the teeth were well calcified, and there were no changes whatever in the hair or nails.

Prevention.—If sufficient care is taken in operations on the thyroid gland extensive damage to the parathyroids should never occur. The rarity of such an event in England is probably due to the fact that thyroid operations are on the whole less extensive than they are abroad, and that most English surgeons make a point of leaving the upper posterior part of at least one lobe. In the case quoted here both lateral lobes seem to have been completely removed and only the middle lobe left behind. In America elaborate care is taken to prevent this accident occurring. In a review of 6700 goitre operations Lahey[18] mentions the fact that parathyroid tetany only occurred in three cases. This he attributes to the fact that at the time of removal all thyroid tissue was carefully examined for parathyroid bodies. If these were found and the findings confirmed microscopically they were at once grafted into the belly of the left sternomastoid muscle. That this technique produced a living graft was confirmed experimentally in dogs by R. B. Cattell and R. L. Mason.

Prognosis.—In this case treatment with parathormone appeared to have no effect on the cataract. This agrees with Jacques's observation on his second case, in which the cataracts continued to progress in spite of treatment with parathormone for eight weeks. Prognosis as regards sight apparently depends on successful surgical removal of the cataracts. There seems to be no reason why this should not be accomplished.

With regard to the tetany a high calcium diet and 12 drachms of calcium lactate daily keep the serum calcium between 5 and 8 mg., and the signs within the limits of a latent tetany. With parathormone as an additional weapon there seems to be no reason why the tetany should not remain completely controlled. At present, while the patient is blind, it is difficult to estimate her power of performing prolonged fine movements, such as knitting or writing. It may prove necessary to give parathormone regularly in the same way that insulin is given in diabetes.

In conclusion I should like to thank Dr. G. S. Haynes for permission to investigate and treat this case as an in-patient, Dr. C. E. G. Wolf and Dr. W. M. Wright for the laborious biochemical investigations they have carried out, Mr. Arthur Cooke for his examination of the eyes, Dr. Ffrangcon Roberts for the radiological examinations, and Dr. W. J. Young for the early history of the case.

A HOSPITAL FOR THE MIDDLE CLASSES.—The Merseyside Hospitals Council (Liverpool) is preparing a scheme for hospital and medical treatment of salaried workers and members of the middle-class generally.

THIRSK LAMBERT MEMORIAL HOSPITAL.—The annual report for the year ended Sept. 30th last shows that the daily cost per head of the 121 in-patients was 7s. 2d., as compared with 10s. 2d. in the preceding year.

TREATMENT OF PUERPERAL SEPTICÆMIA BY SERUM.

BY HAROLD BURT-WHITE, M.D. LOND.,
F.R.C.S. ENG.,

ASSISTANT OBSTETRIC SURGEON, CITY OF LONDON MATERNITY HOSPITAL; SURGEON TO OUT-PATIENTS, HOSPITAL FOR WOMEN, SOHO-SQUARE; CHIEF ASSISTANT TO OBSTETRICAL DEPARTMENT, ST. BARTHOLOMEW'S HOSPITAL.

THIS paper deals with the treatment of cases of puerperal septicæmia by concentrated scarlet fever antitoxic serum. Twenty-seven cases have been treated and eight of these have died—a mortality of 29·6 per cent.

Argument.

Theoretically, two conditions should be satisfied for the successful treatment of a given disease by a serum: the first is that the disease be in a strict sense due to a single infective agent, the second that the remedy contain the corresponding specific antibodies.

It has been confirmed by Armstrong and the author[1] that the great majority of cases of severe puerperal sepsis are due to the well-known hæmolytic organism *Streptococcus pyogenes*. We have suggested that the term "puerperal fever" be restricted to cases due to this streptococcus, for severe and fatal cases are caused almost exclusively by this organism. Further, we advocate that the diagnosis of puerperal fever should be based always on a bacteriological test and in consequence every case treated by serum in the series described in this paper has been proven due to *S. pyogenes* by cultures from the cervix uteri and the blood.

The term "serological identity," as applied to bacterial strains, entails specificity of a very high degree. The identity of all strains of *S. pyogenes* has not yet been determined, but it is certain that several serological groups of this organism occur and that, just as in the case of the pneumococcus, still other virulent strains, not included in these groups, sometimes cause serious illness. The first condition or postulate—namely, that the disease be due to a single cause—would remain unsatisfied, therefore, were it not for the fact that there is evidence that the exotoxins from all strains of *S. pyogenes*, including strains responsible for scarlet fever, erysipelas, surgical sepsis, puerperal sepsis, are very similar if not identical, the toxin from scarlatinal strains being considered the most poisonous and antigenically most efficient. The treatment of diseases due to *S. pyogenes* by scarlatinal antitoxic serum may perhaps be compared with the serum treatment of diphtheria, for there are several serological races of *B. diphtheriæ* but probably a common toxin.

Published Results of Treatment by Scarlatinal Antitoxin.

No published account has been found at the time of writing of treatment of puerperal fever by scarlatinal antitoxic serum although there are numerous references in the literature to the treatment, with varying success, of small groups of cases by other antistreptococcal sera. (Marmorek 1895,[2] Van der Velde 1904,[3] P. F. Williams 1921,[4] H. Bailey 1924,[5] &c.) Antiscarlatinal serum has been extensively used in the treatment and passive prophylaxis of scarlet fever and also in the treatment of erysipelas. It is not possible within the scope of this paper to do more than summarise these results.

O'Brien,[6] in 1927, thus summarised the action of the serum in scarlet fever. "Concentrated scarlet fever antitoxin is of use in the treatment of scarlet fever. No antitoxin or other serum at present available has any direct action on septic complications. The early use of serum probably reduces the length of stay in hospital, but many further observations are required."

Parish and Okell,[7] who are primarily responsible for the preparation of the serum used in the cases described below, found experimentally: (1) That acute and rapidly fatal septicæmia in rabbits due to hæmolytic streptococci obtained from cases of follicular tonsillitis, puerperal fever, cellulitis, &c., could be converted by administration of antitoxin into a subacute and relatively benign infection. (2) That the late complication of arthritis in rabbits was uninfluenced by the injection of serum, even in large doses.

It seems that there is a general impression in favour of the use of antitoxic serum in the treatment of scarlet fever, but both experimental and clinical evidence appear to lead to the conclusion that the later "septic" manifestations are uninfluenced. A similar criticism applies to erysipelas.

Apart from the cases to be described, I consider that the most suggestive and reassuring results have followed the use of the serum by my colleagues in severe surgical sepsis, including acute mastoid disease. It is evidence from these cases, rather than from the treatment of diseases predominantly due to streptococcal exotoxin, which has most encouraged me to persevere, for the clinical aspect of puerperal fever is essentially that of a bacterial invasion rather than a toxæmia.

Emphasis is laid on the fact that the serum used in the cases described here is antitoxic. If the results appear less satisfactory than in the corresponding treatment of diphtheria, it is suggested that the possibilities for serum treatment in severe puerperal sepsis are by no means exhausted. Better success may yet be obtained by using a serum rich in antibacterial, as contrasted with antitoxic, antibodies or a combination of both elements, although attempts so far to prepare such a serum have proved unsuccessful. In any event, it will be shown that large doses of serum may be given safely even in the severest cases of puerperal fever, and often with very striking results.

Method.

In order to test for serum-sensitiveness, 0·1 c.cm. of the serum was administered intradermally half an hour before the main dose. In no case did any reaction occur. This procedure was therefore discontinued after the first 13 cases. Serum in bulk was administered to the first 13 cases intramuscularly, in every subsequent case intravenous injection was exclusively performed. The maximum quantity administered by the intramuscular route on any one occasion did not exceed 30 c.cm. The maximum intravenous dose was 100 c.cm. and never less than 20 c.cm. Injections of serum were repeated as seemed desirable; there did not appear any limit to the number of doses which could be administered to the patient, but the greatest number given was four injections. Serum was given at intervals of not less than 24 hours. Treatment was determined by the patient's needs; a rigor in particular served as an indication for treatment or prolonged high fever with a rapid pulse.

Technique of Administration.

It is unnecessary to give details of the intramuscular method of administration for this has been discarded. Intravenous injection is performed with the customary aseptic precautions.

The apparatus consists of a conical funnel to which is attached a rubber tube two feet long carrying a short needle of wide bore. The patient's arm is exposed; an attendant clasps the upper arm or a bandage may be applied to congest the median basilic vein. The serum is diluted with an equal volume of physiologically normal salt solution and the container immersed in warm water to raise the temperature of the diluted serum to body temperature. The diluted serum is run in slowly; 20 minutes should be allowed for giving 200 c.cm. The puncture may be sealed conveniently by a collodion gauze. The vein should be practically undamaged and is used for future injections.

Reaction of the Patient.

The patient visibly reacts within half an hour to intravenous inoculation; the absence of some reaction is exceptional. In severe cases she shivers violently, her temperature rapidly rises, and may reach 105° F. or even 107° in 15 minutes with great acceleration of the pulse. The women complain of feeling very ill and of faintness. They sweat profusely but, notwithstanding, they are palpably hot to the touch. In two cases there was marked dyspnœa resembling asthma and in one hyperpyrexia was accompanied by a transitory delirium. These symptoms are to be attributed to the immediate effects of the administration of foreign protein and are proportional to the dose. The severe reaction lasts about half an hour and in favourable cases the temperature then falls, often becoming subnormal, with corresponding improvement in the general state.

It is of the most urgent importance that a hypodermic syringe charged with liquor adrenalin hydrochlor. B.P. strength 1 : 1000 be prepared before the serum is given, ready for immediate use if dyspnœa should develop. In such circumstances a dose of 10—15 minims is given subcutaneously without loss of time. Two only of the 14 cases treated by intravenous injection became dyspnœic and were given adrenalin, as a result of which the attack passed off.

The reaction following intravenous administration of serum may be very severe, therefore, but in no case has a fatal result been attributed to it. In any event it will be understood that the women were already seriously ill when treated. Serum rashes of urticarial type developed between the eighth and tenth day after treatment in two cases but without joint involvement.

Response to Treatment.

In favourable cases there are signs of improvement within 6 to 12 hours of treatment, judged by fall of temperature and diminished pulse-rate. The patient often declares herself better for the serum and clinically her aspect improves. This improvement may persist and lead on to recovery and the illness, in cases treated early, appeared actually to be cut short by the serum. Alternatively, improvement may be temporary only and in severe cases the temperature rapidly rises again.

Further administration of serum is usually followed by a favourable response, but the cases which proved fatal were but slightly influenced or not at all, and in one the severity of the rigors which marked the illness appeared to be exaggerated. The character of the response in each type of case is illustrated in representative charts.

Details of Treatment of Puerperal Septicæmia by Intravenous Inoculation of Scarlatinal Antitoxic Serum.

No.	Day of puerperium. Treatment— Begun.	Day of puerperium. Treatment— Ended.	Injections.	Vol. of serum.	Day of R. or D.	Result.
				c.cm.		
1	4	8	3	250	8	R.
2	2	16	3	90	17	R.
3	5	15	4	80	16	R.
4	7	20	3	150	18	R.
5	6	8	2	40	9	R.
6	7	7	1	50	8	R.
7	6	7	2	150	8	R.
8	5	7	2	100	8	R.
9	5	16	4	100	17	R.
10	12	15	3	170	22	R.

	Day after abortion.					
13	6	9	2	130	22	D.
14	6	9	4	210	15	D.

R. = recovery; D. = death.

Details of Cases.

Twenty-seven cases have been treated with eight deaths, a mortality of 29·6 per cent. The details and results of the 14 cases treated by intravenous inoculation are here tabulated.

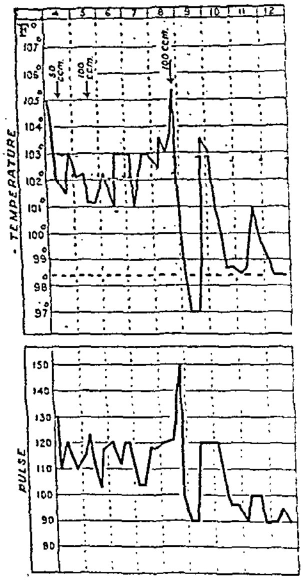
The following three cases, one of them fatal, have been selected to illustrate the effect of serum on the temperature and pulse-rate.

CASE 1 (Fig. 1).—Primigravida, aged 24, delivered at home. Labour normal, two vaginal examinations made. Rigor two days after delivery, temperature rose to 102° F. Admitted to hospital on fourth day of puerperium. Delirious on admission, temperature 105° F., pulse 130. Uterus involuting normally, lochia scanty. *Streptococcus pyogenes* grown in pure culture from the cervix uteri and the blood. 50 c.cm. of serum given intravenously on the fourth day without effect; 100 c.cm. on fifth day without effect; 100 c.cm. on eighth day followed within two hours by a fall of temperature and pulse-rate, the patient becoming rational for the first time since admission. Recovery rapid and uninterrupted, except for a rise in temperature on the following day.

CASE 2 (Fig. 2).—Primigravida, aged 19, delivered in hospital, vertex presentation, labour lasted nine hours. A sore on the patient's hand, from which *S. pyogenes* was recovered, was believed to be the source of infection. Temperature rose to 104° F. the day after delivery. Blood culture on the third day of the puerperium showed pure growth of *S. pyogenes*. 30 c.cm. of serum given on fourth day followed by a gradual fall of temperature and pulse-rate and improved general condition. Temperature 104° F. on ninth day, 30 c.cm. of serum given, and the temperature fell. Temperature again rose sixteenth day but blood culture negative, 30 c.cm. of serum given on this day; the puerperium subsequently normal.

CASE 3 (Fig. 3).—Multipara 3, aged 27. Threatened abortion at third month with hæmorrhage uncontrolled by drugs: admitted to hospital, uterus evacuated. Four days later temperature rose to 104° F. 30 c.cm. serum given on third day of fever, followed by a temporary fall in temperature and pulse frequency. 100 c.cm. serum given on sixth day of fever, again a temporary fall in temperature and pulse. No further serum given; death on twentieth day of disease. A metastatic broncho-pneumonia developed. *S. pyogenes* isolated from blood and uterus on third, sixth, and eleventh days of the disease. Serum treatment was perhaps insufficiently pressed in this case.

FIG. 1.



CASE 1.—Temperature chart from the fourth to the twelfth days of the puerperium, showing response to an injection of 50 c.cm. serum and two injections of 100 c.cm.

Bacteriology.

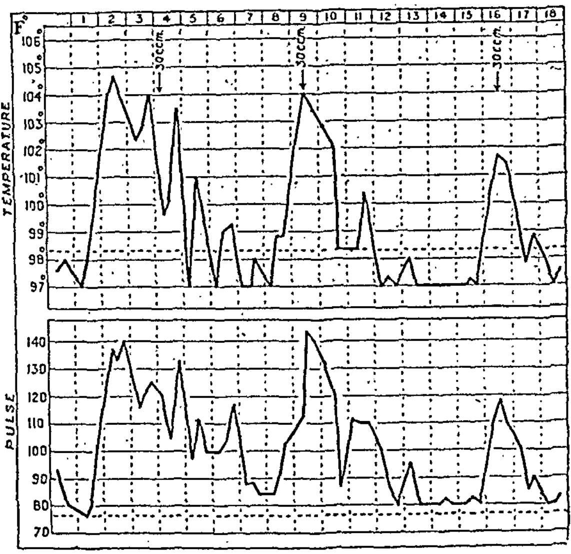
A blood culture and cultivations from swabs from the uterus were made in every case so soon as observation began, usually just prior to administration of serum. In every case typical *S. pyogenes hæmolyticus* was recovered from both sources. In six cases an attempt was made to estimate the number of streptococci present in the patient's blood. Half a cubic centimetre of the freshly drawn blood was spread over the surface of a blood-agar plate kept in readiness by the bedside. Quantitative blood cultures were made day by day in three cases which recovered and the number of organisms per c.cm. of blood was found to diminish as the patient's condition improved. One fatal case showed 75 colonies per c.cm. on the third day of the disease and on the seventh day 150 colonies per c.cm. In a second fatal case 100 colonies per c.cm. were grown on the fourth day. With increasing experience it may be possible in future to base a prognosis on the severity of the blood infection and so establish a standard by which the results of special treatment may be estimated.

The number of observations made was small, and it has not been possible as yet to compare the bacteriological technique used with other recognised quantitative methods of blood culture.

Discussion.

The importance of advancing the treatment of puerperal *septicæmia* is great and justifies publication of a relatively small number of cases at this early stage. I believe that the patients are definitely the better for scarlatinal antitoxic serum, but recognise that other methods of treatment have raised similar hopes in the minds of those who have used them. It seems that, to be successful, treatment should be begun at the earliest possible moment, and furthermore that persistence in the treatment is essential. It is perhaps permissible to state that courage is required in the application of the remedy for the patients are often desperately ill, and the immediate result of intravenous injection of the concentrated serum is at times very severe.

FIG. 2.



CASE 2.—Temperature chart from the day of delivery to the eighteenth day of the puerperium, showing response to three injections of 30 c.cm. of serum.

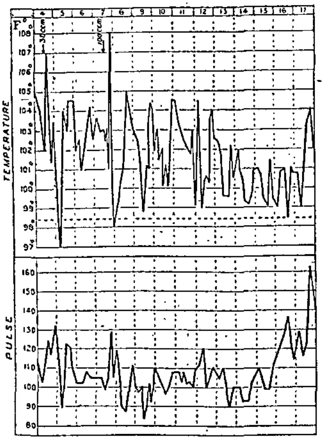
Results claimed for any specific serum are always open to the criticism that "protein-shock" is responsible for the effects produced rather than the neutralising action of specific protective substances. In this connexion it would have been instructive to have treated similar cases by concentrated horse serum—that is to say, by administration of the "vehicle" without the "remedy"; this procedure is contemplated.

Not the least of the difficulties in estimating the value of the special treatment of sporadic diseases such as puerperal fever is the small number of cases available at any one time and in any one place. Statistics of the mortality from puerperal septicæmia are to be found in two reports,[8] presented to the British Congress of Obstetrics and Gynæcology in 1925, respectively by a London Committee on the prognosis and treatment of puerperal sepsis and a committee of the North of England Society for Obstetrics and Gynæcology on puerperal blood infections. Rules were made and observed by both committees by which cases should be judged suitable to be recorded as blood infections.

The London committee studied 247 cases, amongst which the *mortality* was 36 per cent. Of these, 53 cases were definitely proven to have streptococci in the blood; the exact variety of streptococcus was not stated. The *mortality* in this group was 66 per cent. The Northern committee studied 154 cases; the *mortality-rate* was 76 per cent. The blood was examined during *life* in 75 of these cases and streptococci grown in over 65 per cent.; the mortality in this group was not stated. In 22 cases of which full particulars were available and were tabulated, 19 died, all with positive blood cultures; the three survivors showed negative blood cultures.

With regard to special treatment, the London committee report 33 cases conforming to the rules, treated by antistreptococcal serum and injections of quinine and a mortality of 18 per cent. Eleven patients were treated by intramuscular injections of quinine alone and all recovered; 14 patients were treated with antidiphtheritic serum and only one died; three patients treated by neosalvarsan and collosal iodine all died. The Northern committee report 101 cases treated by antistreptococcal serum and give an analysis of the quantities and details of administration of the serum. One hundred and four cases treated by antistreptococcal and other sera, on which operations were also performed, showed a mortality of 72 per cent., and 47 cases treated by serum, on which no operation was performed, a mortality of 76·5 per cent. In view of these widely varying results, no safe conclusions can be drawn from the results recorded in this paper—namely, 27 cases treated and a mortality of 29·6 per cent. Bright hopes may have been founded on the total recovery of the 11 cases mentioned above, treated by intramuscular injection of quinine, or on the 14 cases with only one death treated by antidiphtheritic serum, yet neither method has become generally established. Far-reaching experience coupled with the most rigid impartiality must indeed be exercised in assessing the value of special treatment. The conclusion seems forced that in the absence of a method of accurate estimation of the severity of a given case of puerperal septicæmia the existing statistics are of doubtful significance.

FIG. 3.



CASE 3.—Temperature chart from a fatal case of septicæmia following abortion. Two injections of serum, of 30 c.cm. and 100 c.cm., were given.

My thanks are due to the Wellcome Physiological Research Laboratory for the generous gift of serum and for cordial interest. I am indebted to the Staff of the Obstetrical Department of St. Bartholomew's Hospital and to my colleagues at the City of London Maternity Hospital for cases, and to Dr. R. R. Armstrong for help in drafting this paper.

Since completing this paper I have treated three cases, in all, of puerperal septicæmia with the same serum and all proved fatal. I also have had four cases of severe infections with organisms other than *S. pyogenes*, all of which responded to treatment with this serum. Doubt therefore exists whether the serum acts specifically or not.

NOTES ON THE TREATMENT OF
GONORRHŒA IN THE MALE.

BY H. D. LIVINGSTONE SPENCE, M.D.,
M.CH. QUEEN'S UNIV., ONTARIO,
LATE CHIEF ASSISTANT, SKIN DEPARTMENT,
ST. BARTHOLOMEW'S HOSPITAL.

GONORRHŒA restricted to the anterior urethra is a trivial complaint. Its importance rapidly increases as infection spreads and the posterior urethra and contiguous parts are successively involved.

Our first care is to support the patient's immunological defences by regulating personal habits and activities, and by rendering the urine at once less irritating and less favourable to the multiplication of gonococci by dilution and alkalisation. Local measures will aim at destroying germs and controlling inflammation without injury to the urethral lining.

It is questionable if the dietary restrictions commonly imposed are of much practical value. The withdrawal of meat, tea, coffee, ordinary condiments —and tobacco—is sufficiently a deprivation to cancel any theoretical gain, and excellent advice about rest and the speculative advantages of a milk diet chiefly adds to the characteristic mental depression of the patient. Competitive games, dancing, and equitation should be given up, sexual excitement is to be avoided, and alcoholic beverages, ginger ale, ginger beer, and cider are definitely harmful.

The ideal antiseptic for use in the inflamed urethra would be clean, non-irritating, penetrative, stable in aqueous solution, and effective alike against the gonococcus and any secondary organisms without being toxic to the host. At present no single preparation fulfils these requirements. Potassium permanganate is a feeble germicide, colours the skin and clothing, and seems to encourage intraurethral and paraurethral complications, its principal effect being to provoke a rapid and intense œdema undesirable in the early inflammatory stage. Mercurochrome is an exceedingly interesting experiment, mercury being linked to a dye in an effort to produce a deeply penetrating antiseptic. It penetrates well but stains everything it meets an almost indelible red, is distinctly irritating, and, as a urethral antiseptic, disappointing. Acriflavine also stains, and is subtly irritating, but is otherwise a quite useful all-round germicide, penetrative to a degree, unaffected by urine, and to be recommended for occasional rather than routine use. In a mixed infection it is my practice to employ separate agents for the gonococcus and saprophytes, *used together if chemically compatible*, seriatim if otherwise, the gonocide being frequently changed to avoid "fastness." Mercury oxycyanide, for example, is quite good against the staphylococcus and other followers, but an indifferent gonocide, while the innumerable silver colloids provide many reasonably effective gonocides, often not too clean, but bland and non-irritant when freshly prepared, and eminently suitable for use in the inflamed urethra. Among the milder silver preparations, indicated in the early stage as gonocides, the writer favours argyrol, neoreargon, neoprotosil, cargentos, and collosol argentum, to be succeeded by albargin, hegonon, novargon, protargol, acriflavine hydrochloride, thallin sulphate, or silver nitrate later on as symptoms decline, and a little stimulation seems desirable.

Use and Abuse of Irrigation.

When anterior gonococcal urethritis terminates favourably damaged epithelium is shed, tension in the tissues diminishes, gonococci vanish, the meatal discharge lessens and stops, pus cells are no longer recoverable from the urine, and the urethral mucous membrane resumes its normal appearance. This is clinical cure and in established infections should be complete in three or four weeks. The failure of symptoms entirely to disappear may be due to over-treatment, the first urine containing light tissue detritus and perhaps just sufficient muco-purulence to render it slightly hazy. The presence of heavier flakes and many pus cells, and, particularly, the discovery of gonococci, indicate the persistence of infection deep in the tissues, in Littré's glands, the lacunæ of Morgagni or adventitious passages, or that infection has reached the posterior urethra. The latter development may be heralded by terminal hæmaturia, signifying an acute onset, and since much more serious events are now in prospect, correct management at this point is of obvious importance. The worst thing one can do is to attempt to irrigate the bladder from the meatus, infection of the seminal vesicles and prostate being in such case almost inevitable and extension to the epididymes likely. A better plan is to insert per rectum a suppository containing morphine sulphate (gr. ¼) and atropine sulphate (gr. 1/75), to be repeated in four hours, add tincture of hyoscyamus to the alkaline mixture, and omit all local treatment for 48 hours. At the end of this period the anterior urethra should be washed first with half-saturated acid boric solution and then with collosol argentum, after which a sterile No. 8-E. soft rubber catheter is introduced beyond the cut-off muscle and an ounce or more of collosol argentum allowed to trickle slowly into the posterior urethra and bladder, to be retained. This procedure is repeated in 24 hours, and thereafter 1 per cent. protargol may be substituted for a day or two, or retrograde lavage at once commenced with silver nitrate, 1–5000, containing 1 per cent. acid boric. More often posterior urethritis begins insidiously and pursues from the first an essentially chronic course.

While infection is restricted to the anterior urethra, local treatment is performed using a small all-glass acorn-tipped bulb or piston syringe. With the extension of inflammation beyond the bulbous portion to the membranous and prostatic urethra antiseptics must be carried past the cut-off muscle, and the method of their introduction is of some importance. With the Janet method of irrigation from the meatus there is the danger of injuring the inflamed mucous membrane through over-distension, and Kohnstam and Cave[1] have shown how easily fluid is driven into the seminal vesicles during forced irrigation of the bladder. For these and other reasons the retrograde method of lavage is preferable, the fluid being introduced into the bladder through a catheter or tunnelled sound and then voided naturally, when the tendency, if any, is to remove material by aspiration and contractile pressure from soiled glandular ducts.

The secretions of the seminal vesicles and (usually) the prostate are alkaline in reaction, a circumstance which might be expected to confer a certain protection against gonococcal penetration; but unfortunately does not do so. Inflammation may remain confined to the prostatic and ejaculatory ducts and, being catarrhal only, give little evidence of its existence. Where it is progressive the ducts become more or less occluded, drainage is impeded, the glands enlarge and become diseased. Owing to their vascularity, implication of the seminal vesicles is a threatening development, as toxic absorption is increased, and gonococci may eventually reach the general circulation; more commonly, however, there is extension along the ductus deferens to the epididymus. The advance of infection along the prostatic ducts leads to parenchymatous or interstitial prostatitis, the latter form proceeding to abscess formation.

Complications like epididymitis and hyperacute febrile inflammation of the prostate gland or seminal vesicles require the temporary cessation of treatment per urethram in favour of chemotherapy or vaccinotherapy, either of which is superior both in immediate and ultimate effects to operative or other methods in the writer's experience. The use of metals in this connexion is admittedly empiric, although there is an experimental basis for the belief that certain inorganic substances upon reaching the blood stream act like living or dead bacteria in inducing the leucocytes to liberate a non-specific bactericidal or bacteriostatic element. In practice it is often surprising how rapidly and completely acute epididymitis subsides after two or three intravenous injections of sulfarsenobenzene, and hyperacute inflammation of the other glands accompanied by temperature is almost equally well controlled by chemotherapy without, however, any marked effect being produced upon the general course of the disease.

Massage and the Passage of Sounds.

In health the seminal vesicles are difficult to distinguish per rectum, but they are readily palpated in disease, and there is a variable amount of conservative inflammation in the periglandular tissues. Depending upon the period and character of the infection, one or both lobes of the prostate may be enlarged, smooth and tense or, instead, feel nodular, suggesting a collection of lobulated masses. From the standpoint of remedial treatment, however, it is expedient to regard the inflammation of both prostate and vesicles as secondary, the primary lesions being in their ducts and the restoration of their calibre a necessary prelude to cure.

One or two quite light strokes are sufficient to empty a seminal vesicle whose duct is patent, and massage of the prostate gland should be of the gentlest description, a series of joined copy-book O's centripetally stressed from above downwards, and never the "firm downward pressure" of the older text-books. Massage at all violent readily injures these friable glandular tissues, and is more likely to retard than assist recovery. Nor is it necessary or desirable to attempt mechanically to empty either prostate or vesicles at each session if the trouble is, for practical purposes, obstructive.

There are experienced specialists who seem to counsel the abandonment of massage altogether, but it is a little difficult to accept this view. Light rectal massage seems needed to maintain tone and contractile power, combat stasis, and assist in the removal of cellular deposit, but the first consideration is to secure resolution of the inflammatory exudation in the urethral region so that adequate drainage may be re-established.

The passage of cold steel sounds, if properly timed, is a valuable aid in accelerating resolution and more effective than the use of dilators. It is often thought that the benefit accruing from instrumentation is wholly to be attributed to the mechanical stretching of the urethral canal, hidden foci being uncovered, crypts and folds ironed out, the lacunæ and Littré's glands pressed free of their contents. This explanation, however, is incomplete, for these are only incidental and relatively superficial effects of the passage of steels, more important being the influence upon plastic exudation, the resorption of which is actively promoted. In chronic anterior urethritis the parts become semi-indurated, and if inflammation persists connective tissue cells will gradually replace small cells in the subepithelial area, converting "soft" into "hard infiltration," found in organic stricture. The last, however, is a terminal condition and comparatively remote, and at an earlier stage infection and increasing tension disturb glandular function, the mucous membrane is irregularly swollen and dull, its folds are less distinct, and there is a patchy loss of surface epithelium, while layers of new cells are laid down beneath as a result of continued irritation. Analogous changes occur in the infected posterior urethra; the verumontanum is engorged and soft and the prostatic and ejaculatory ducts ringed with inflammation, and more or less occluded. It is true that a steel may, and does, expose an infective focus here and there as it traverses the urethra, but its real importance is the circumstance that it meets the first therapeutic indication in chronicity—namely, stimulation. After a preliminary blanching the urethral lining becomes congested, leading to a lively flare-up of the previously sluggish infective process. These symptoms decline after a few days' retrograde lavage, and with the ebb-tide some recession of the underlying inflammatory condition takes place. The next steel awakens less reaction, a third still less, until finally upon total resolution meatal discharge ceases, the urine clears, and the patient is pronounced clinically well.

---

[1] Kohnstam, G. L. S., and Cave, E. H. P.: Radiological Examination of the Male Urethra. London. 1925.

The post-gonorrhœal "morning drop," whatever its bacterial content, is always suspect. It has led abruptly to the divorce court; a longer and well-worn path ends at the gynæcologist's. Treatment of the male gonorrhœic should be continued until subjective and objective signs of the disease have completely disappeared, the five-hour urine is perfectly clear, and white cells are no longer recoverable in significant numbers from the genito-urinary tract. After two months the complement-fixation test should be declining in strength or negative, and if the patient also registers a gain in weight his future may be regarded with confidence.

Clinical and Laboratory Notes.

THE TREATMENT OF MALIGNANT TUMOURS WITH RADIUM CATGUT.

BY DR. EUGEN JOSEPH,
PROFESSOR OF SURGERY IN THE UNIVERSITY OF BERLIN.

THE beneficial influence of radium on malignant tumours is probably greatest when the radium is most evenly distributed and left for the longest possible time in the body or the tumour itself. Various methods have accordingly been invented by which radium is implanted in minute tubes throughout the substance of the tumour, especially when there is no prospect of a permanent result from operation. Implantation has therefore been chiefly employed in carcinoma of the bladder, either alone or after operation. The methods in use have the drawback, however, that the seeds are usually extruded from the tissues.

It is highly probable that the effect of radium is more powerful and lasting if the radium is introduced into the tissues themselves than if it is simply applied to the surface in the neighbourhood of the tumour, when the rays in the overlying tissues are bound to exhaust much of their strength. For this reason radium has given its best results in quite superficial tumours of the skin and of the subcutaneous cell tissue, such as telangiectatic nævi and papillomata of the skin. When radium is left in the tissues after partial or complete removal of the tumour, its effect becomes very much greater. Radium needles buried in the tissues are employed for this purpose, but they have the disadvantage that they are foreign bodies with an irritant action on the tissues and must therefore be removed after a certain time. They are, in fact, often extruded spontaneously. The mesothorium needles in common use at the present time remain in place well, but have not nearly such a powerful action as radium itself.

The retention of radium in the tissues has its own dangers. Rats die a certain time after being injected with a quantity of radium salts, and it is known that the largest quantity of radium which a person weighing 70 kg. can tolerate without grave danger is less than half a milligramme. This is probably why, apart from its expense, the method of leaving radium in the body, except in needles, has not been adopted. Nevertheless, it is undoubtedly possible by this means to prevent a certain proportion of recurrences and local recurrences of the growth. If, for example, the abdominal wall were sewn up after the removal of a tumour with radium catgut or radium silk, the stitch infections which occur so commonly in this region and in the soft parts of the extremities after the removal of a sarcoma or carcinoma would in all likelihood be avoided. Radium catgut is better than radium silk because it is absorbable. The radium should be so distributed over the gut that the dose in the length to be used shall not exceed half a milligramme. The efficacy of the method is shown by the following clinical observation.

The patient, a man aged 25, suffered from an extensive inoperable adenocarcinoma of a kidney. The tumour was about the size of a child's head and was surrounded by glandular metastases, one of which was the size of a normal kidney. I was nevertheless able to remove the tumour and some of the metastases together, but I had to leave the remainder, partly because their removal would have made the operation dangerously long considering the very weak condition of the patient and partly because they were technically inoperable on account of the adhesions they had formed with the large vessels. As I expected a considerable amount of hæmorrhage from this large parenchymatous wound I did not close the incision completely, but packed it with gauze in order not to leave too large a cavity. A few stitches were inserted in the overlying soft parts to keep the gauze in place.

It was easy to foretell that the wound would not close for some time and that the tumour would grow again from the remaining lymph glands and rests. This, in fact, took place. The cavity showed no signs of healing and looked like every other wound from which a large malignant tumour had been partially removed. There was no prospect of inducing it to heal by the ordinary methods. The tumour began to grow again like a fungus and, since it had no skin covering, to ulcerate and suppurate.

The condition was so desperate that I thought it worth while to try the effect of a "secondary" suture with catgut which had been steeped in radium substance. This was a pure experiment and I knew very little about either the preparation of catgut with radium or the proper manner in which to apply it. A certain amount of radium was certainly wasted, which was probably rather a good thing, for we had used 3 mg. of radium substance for about a metre and a half of gut. I closed the walls of the cavity with a purse-string suture, using about half a metre, and the fact that I did not use more prevented my exceeding the limits prescribed by Gudzent. Even so the patient showed very marked symptoms in the course of the next few days. He felt unwell, had no appetite, and was very excited and weak. After about a week these symptoms disappeared; moreover, the desperate condition of the wound began to improve. Apart from the fact that the surface had been drawn closely together with the purse-string suture, secretion gradually diminished; vigorous red granulation set in, although no other treatment was given, and the wound closed completely and healed over. The patient was discharged to his home apparently cured. I am fairly certain that without this procedure a fungoid, putrescent, ulcerating tumour would have formed in the wound and killed the patient in a short time, either by eroding the vessels or by exhausting his strength. Naturally I am doubtful whether he will remain well, but it is certain that if I had not performed the operation and followed it with the radium suture he must have succumbed.

Treatment with radium catgut can be carried out in a number of ways: the tumour may be excised and the wound closed with radium catgut, or an inoperable tumour may be threaded across and across with lengths of radium catgut, the dosage not exceeding 0·5 mg. The latter method is only applicable to inoperable tumours. It is not without its dangers, for cancer patients are usually in poor general condition. The surgeon should, therefore, both prepare the catgut and apply the treatment himself. The method is far more difficult than deep irradiation and should not be left to an unqualified person.

Another consideration is the cost of the material. Estimating the amount of radium used at half a milligramme at the most, and remembering that some of it must inevitably be lost, it is necessary to start with at least one milligramme, which costs £10; moreover, the radium remains finally divided in the body and cannot be used again on other patients. And thus the method is unfortunately inapplicable to all cases of carcinoma. When cost forbids the use of radium, the catgut may be prepared with other substances which are unfavourable to the growth of tumours. Carl Lewin has introduced a compound which he calls "Introcid," a combination of iodine and cerium, one of the heaviest metals, with which catgut can be impregnated and which is considerably cheaper. Nevertheless, I shall continue whenever possible to treat inoperable tumours and the site of operation with freshly prepared radium catgut, and I expect a considerable degree of success and prolongation of life in cases which could not be benefited without the introduction of radium into the tissues. I have hopes that this method may prove a valuable standard auxiliary to the operative treatment of cancer in general.

A CASE OF

PERNICIOUS ANÆMIA NOT RESPONDING TO LIVER TREATMENT.

By A. C. Hampson, *M.C.*, M.D. Camb., M.R.C.P. Lond.,

ASSISTANT PHYSICIAN TO QUEEN MARY'S HOSPITAL, STRATFORD.

In The Lancet of Nov. 2nd, 1929 (p. 935), in an annotation on a paper by Dr. P. Emil-Weil (*Le Sang*, 1929, iii., 426), the question is raised: "Are there any cases of pernicious anæmia which will not respond to liver?" Pointing out that we have at present three criteria of pernicious anæmia—namely, achlorhydria, hæmolysis, and an increase in the mean size of the red cells—the annotation says that as Dr. Emil-Weil gives no information on the last two points "it would be rash to amend the aphorism that anæmia which will not respond to liver is not pernicious anæmia."

The following case, which has been under continuous observation at Queen Mary's Hospital for over two and a half years, is of interest in that it shows all the criteria mentioned yet has not reacted to liver treatment, though very large doses have been given.

A man, aged 50, first complained of giddiness in 1925. He was treated by his doctor for anæmia for some months. In October, 1926, he had 14 teeth extracted, and the extraction was followed by considerable hæmorrhage. From that time he had become progressively weaker. He was sent to Queen Mary's Hospital on Feb. 25th, 1927. On examination he was found to be a well-covered man, very anæmic, with a lemon-yellow colour of the skin. The spleen was palpable. His few remaining teeth were septic.

Examination of the blood showed: hæmoglobin, 32 per cent.; red cells, 1,600,000; white cells, 4200; polymorphs, 30 per cent.; lymphocytes, 68 per cent.; eosinophils, 2 per cent. Platelets were few. The mean diameter of the red cells was 8·2 μ, and the Price-Jones curve showed the typical distribution of pernicious anæmia. The cells themselves showed considerable variation in size and shape. Van den Bergh's test showed a negative direct and a positive indirect reaction. A fractional test-meal revealed a complete achlorhydria. Examination of the fæces for parasites gave negative results, and otherwise the stools appeared normal.

The remaining teeth were gradually extracted, and associated with this and treatment other than the administration of liver the blood condition showed slight improvement. Two blood transfusions were done, and at the beginning of August, 1927, the hæmoglobin had risen to 70 per cent. A fortnight later it had fallen to 50 per cent. Liver treatment was then commenced, and has since been given without interruption. This treatment produced no immediate rise in the value of the hæmoglobin, though later there have been periodic rises, apparently quite independent of the treatment. Taken as a whole the level of the hæmoglobin has become progressively lower, being at the present time 25 per cent. A consideration of the blood examinations suggests that the liver diet may have produced a temporary fall in the colour-index during the first few weeks. During the same period the mean diameter of the red cells became less (but still above normal). Such variations occurred in other cases before the days of liver treatment, and that this result was at all events only temporary is shown by the fact that since March, 1928, the colour-index has never been below 1·1, while at times it has been as high as 1·4.

The test-meal and the van den Bergh reaction have been repeated several times with results similar to those recorded above. On several occasions it has been necessary to resort to transfusion. In July of this year he was found to have pus in the ethmoidal cells. This has been dealt with without improvement of the condition of the blood. The patient's weight has been well maintained throughout the whole period. The liver for this patient's diet was prepared in the same way as that used for other patients suffering from pernicious anæmia who have been in the hospital during the last two and a half years. The other patients readily responded to treatment.

The majority of the investigations recorded above were conducted by Dr. Arthur Davies and Dr. L. Hewlett, to whom I am much indebted.

INTERNAL SPLINTING FOR FRACTURES.

By R. E. Pascal,

INTERNE DES HÔPITAUX DE PARIS.

It is well known that efficient immobilisation offers the best means of relieving the pain of fractures and of ensuring bone consolidation. Absence or delay of bony union is due to various factors, known and unknown. An examination of radiograms shows that there is a correlation between these defects of repair and the peculiar rarefaction and loss of calcium known as osteoporosis. This condition is often seen after operations on the skeleton, especially when two bony fragments have been united by a piece of metal. The metal has naturally been blamed, but osteoporosis may appear in one case and fail to appear in another when the conditions seem identical.

Robineau and Contremoulins,[1] after long study of the modifications in bone seen radiologically after operations for fracture of the neck of the femur, have established certain biological laws which may be summarised as follows. Osteoporotic changes do not occur after splinting with beef bone or non-oxidisable metal: (1) when the splints have been mounted and fixed in strict accordance with the laws that a first-class mechanic would apply in setting up a delicate piece of mechanism; (2) when the splints have been calculated to withstand the strain to which they will be submitted; and (3) when the splint and the pieces of bone which it unites are not submitted to premature mobilisation or any disturbance which might compromise the good position originally obtained.

This is quite a new conception; an example will make it clear.

A fracture of the neck of the femur is treated surgically and all goes well. The patient gets up too soon and disturbs the neighbourhood of the fracture, which is not yet completely consolidated. A few days later he has some pain and X rays show commencing osteoporosis around the screw. If the injured limb is again immobilised, the pain and the osteoporosis soon disappear and full consolidation is obtained.

The results got by Robineau and Contremoulins afford the best proof of the importance of absolute fixation of bony fragments and splints in order to prevent any change in the bony tissue.

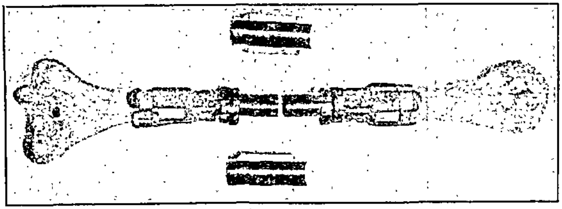
---

[1] Robineau, M., and Contremoulins, G.: Note presented by Dr. Bazy, Compt. rend. Acad. des Sci., 1925, clxxx., 1543.

Devices used by Robineau and Contremoulins.

For repairing the shafts of long bones they do not use the strips of Putti and Parham nor the plates of Lambotte and Shermann, because from a mechanical point of view these do not offer sufficient resistance. On the principle that a given mass is stronger when disposed as a hollow cylinder than in any other form, they constructed sheaths to enclose the broken bone completely and to grasp it tightly. The length of the sheath depends, of course, on the size of the bone, the direction of the fracture, and the number of the fragments. Correct adjustment is easy, for the sheath only needs fitting and tightening. No other immobilisation apparatus is required, even for a fractured femur. The joints may be moved a few days after operation, and bony union is secured earlier than after bloodless operation or other surgical techniques.

FIG. 1.

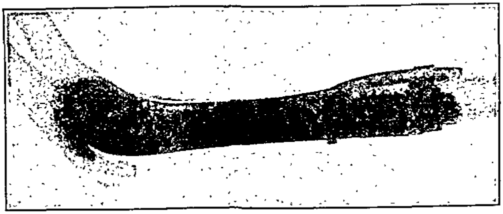


Bronze sheaths used for joining separated fragments of bone.

After arthrodesis and resection of the knee-joint, when ankylosis is desired, Contremoulins and Robineau fix the tibia to the femur by two beef bone screws set crosswise. Here again no immobilisation is required, and 45 days after the operation the patient can walk about and resume active life. His period of convalescence is thus halved. There is considerable difference between healthy and diseased bone; in resections for tuberculosis the bones are generally decalcified and soft and the correct placing of screws is very often impossible. Osteoporosis, which never appears in perfectly healthy bone, may then occur round the screws, but so far it has always been too limited to retard bony union.

The long metallic sheaths used for fractures had proved that the Durville bronze used was quite well borne by the tissues. Only three times during eight years had it been necessary to remove the sheath, and healing had been obtained without disturbing it in infected suppurating fractures. Contremoulins and Robineau thought, therefore, that they could safely enclose the bones in an even more massive material. After subtrochanteric osteotomy of the femur two independent pieces of metal are screwed into the two fragments; the screws are split longitudinally and the points separate in the medullary cavity, thus acquiring a very strong hold (Fig. 1). The two pieces of metal are then joined by a gear-toothed articulation, which allows the surgeon to correct any faulty alignment and put the limb into the correct position before the device is locked. A bone graft is added to the metal splint to ensure bony union. The patient can leave his bed six to eight weeks after operation without ever having been in an immobilising apparatus. There is no fear of secondary deviation or a return of the original deformity.

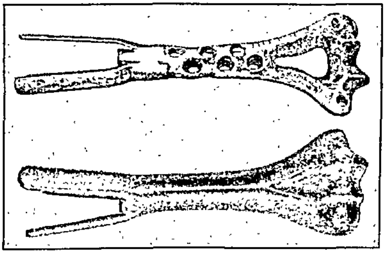
FIG. 3.



Radiogram, taken five years later, showing the substitute (see Fig. 2) in position.

Finally, Contremoulins and Robineau have solved the problem of treating cases in which there has been considerable loss of bone substance. Their first case was treated four and a half years ago. The lower third of the humerus was replaced by a mechanical device made of steel covered with dentist's rubber (Fig 2). Success depended on secure union between the prosthetic device and the bone. To this end a steel dowel covered with ebonite was driven with great care but considerable force into the medullary cavity of the resected humerus. To prevent splitting as a result of violent lateral movement, three processes mounted on the prosthetic piece were screwed to the surface of the humerus and held in place by a ring of aluminium bronze (Fig. 3). Repeated X ray photographs failed to reveal any osteoporosis; indeed, after two years there was a slight condensation of the humerus around the metal. The patient has full use of his arm, works as an errand man with a tricycle, and plays the banjo.

FIG. 2.



Steel substitute for lower third of the humerus (covered with dentist's rubber).

The mechanical adjustment of metal devices constitutes a new surgical method which will have many difficulties to overcome, for it can leave nothing to chance. Each case requires elaborate investigation. X ray measurement of bone,[2] special design of pieces for their particular duties, a carefully prepared scheme of operation which must be strictly followed, a peculiarly thorough sterilisation—especially of rubber-covered devices—and rigorous asepsis. These difficulties are of little importance when weighed against the benefits of retaining a limb otherwise doomed to amputation, and of restoring functional activity in a case where all the classical operations would fail. There is still scope for advance. It may be possible in time to replace an entire bone with metal, and to make a complete joint endowed with normal movement.

[2] Contremoulins, G.: Arch. d'Elect. Méd., 1901; Ann. d'Electrobiol. et de Radiol., 1904, Nos. 5 and 6; Presse Méd., 1923, Nos. 74 and 78.

Results.

The sheaths or sleeves for repairing fractures of bone shafts have given excellent results since 1921. In only three out of over 100 cases thus treated have they had to be removed, and this was done very easily. Many of the patients had compound fractures but this did not prevent sound consolidation. The sheaths are quite well tolerated and I have never observed pseudarthrosis. The callus grows inside and outside the sleeve; on the femur very extensive callus-formation may be seen outside the sleeve. The big internal splinting devices set by us have never yet had to be removed, though it is now more than five years since the first case was treated in this way.

Medical Societies.

SOCIETY OF MEDICAL OFFICERS OF HEALTH.

AT a meeting of this Society on Dec. 20th, with Dr. J. J. BUCHAN, the President, in the chair, a discussion on the

PUBLIC HEALTH SERVICE AND ITS FUTURE

was opened by Prof. H. R. KENWOOD. He began by saying that the goal of the Public Health Service was distant but clearly defined. It was represented by a future in which the mind of the public should be attuned to public health precepts and practice; in which general practitioners would be concerned with public health measures of preventive medicine; and in which there should be the maximum efficiency of administration with the minimum of overlapping. That there were flaws and gaps in the present scheme no one present need be reminded; as an illustration he would mention the tuberculosis system, which was poorly organised for control of early cases and for after-care, but which was responsible for such excellent work in the intermediate stages. The need here was for earlier diagnosis and treatment and more efficient after-care. To give an illustration in another direction, Sir George Newman stated that at 5 years of age a quarter of the children entering school required medical attention. At present the public health scheme lacked completeness and comprehensiveness. A national scheme of health education was required, in which the Society would play an important part, and such a scheme would depend largely on the coöperation of the family doctors; no services should be undertaken by the health authorities which the general practitioners were able and willing to carry out. On the other hand, it was essential that general practitioners should be imbued with that understanding of preventive medicine which at present they lacked. Experience of general practice was essential to a public health official, and the National Health Insurance scheme gave opportunities for coöperation between panel doctors and local health authorities.

Status of the Public Health Service.

The efficiency of the public health service, as well as its status, depended on the quality of those who entered it. At present there was disappointment and discontent among the assistant medical officers of the service, owing to the insufficiency of the salaries offered by the local authorities. Only a few of the workers could hope to become heads of departments, and many of these had been in office for years without hope of improving their prospects. As a rule an assistant medical officer had no hope of promotion unless his chief retired; applications for senior posts elsewhere usually resulted in disappointment, owing either to local competition or because the experience of the applicant was considered to be "too narrow." An assistant medical officer began work at a salary of £500 or £600 a year; after eight years he might rise to £700; and after another five years the local authorities had it in their power to consider whether they would augment his salary or not. In any case it should be made clear that this only covered certain defined duties, and anything outside those duties should receive extra remuneration. Medical officers of health should allot as many duties as possible to members of their staffs, in order to give them opportunities to raise their salaries, augment their experience, relieve the monotony of their work, and increase their chances of obtaining better posts. Medical officers of health were overloaded with administrative work, and should delegate work outside the office to assistants. He had heard them accused of missing admirable opportunities for research, but the truth was they had no time. He would urge all medical officers of health to take every opportunity of bringing the work of their assistants before the authorities; this course raised the quality of the team work and helped juniors to obtain better posts. A new superannuation scheme was required; officers should be able to serve more than one public body without loss of superannuation. Also he would protest against the age-limit at 40 years, a period at which officers were most valuable in point of experience.

Prof. W. W. JAMESON said he would like to refer to the past; it was only 50 years since the local sanitary authorities had been put under statutory obligation to appoint public health officers, and they had as a rule appointed the local poor-law medical officer, who knew nothing of preventive medicine. Forty years ago the county and county borough councils had come into being; but public health service as it is to-day dated from 1907. In 1919 and 1920 many new appointments were made, until now there were 1500 to 1600 whole-time medical officers in England and Wales, of whom only 360 were medical officers of health. For some time past a campaign for higher salaries for assistant medical officers had been in progress. Advances had been made in the work and difficulties overcome; as a result of the Local Government Act, coming into force next year, the medical officers of health would be able to coöperate on a larger scale with the local authorities and with voluntary hospitals in their districts. The public health service was the only service requiring a special post-graduate degree in its members, and students in hospital were at present instructed too little in preventive medicine. At the present time welfare and maternity posts were often filled by persons lacking the diploma of public health, while their junior unqualified assistants had done a six-months course in this subject. Districts had formerly been much too large for adequate administration by the medical officer of health, and this was still the case to some extent; thus one area consisted of 15 districts and 500 square miles, without provision of travelling facilities. Prof. Jameson thought that some part-time posts might be occupied by general practitioners, in order that they might have a direct and practical interest in the work. He agreed that there were plenty of opportunities for research but too little time. The opening of the new School of Hygiene, with a Government guarantee of adequate support, was significant of the interest which preventive medicine was awakening.

Discussion.

Dr. A. K. CHALMERS said that the new Act was the opening of a new scheme; to retain the best men in the service salaries should be scaled. The opportunities for research were wide and not confined to the laboratory. Diphtheria was more prevalent in

Scotland of late years, while scarlet fever, though at present of a mild type, appeared to be unaffected by public health activities. These offered two interesting fields for investigation.

Dr. T. SHADIK HIGGINS (Cape Town) described the present position of South Africa with regard to public health. The scheme, he said, was modelled on the British service, but did not control the school medical case, and had no connexion with poor relief work. The work was complicated by the existence of a white colony and a large half-breed community, as well as the native inhabitants. The death-rate among the half-breeds or "Cape coloured" cases was much higher than among Europeans, as was also the susceptibility to tuberculosis. He attributed their condition to insufficient wages.

Dr. E. T. NASH said that in reply to a questionaire sent by post to assistant medical officers in the service he had ascertained that the average age of these members was 39½ years, that 63·5 per cent. were married, and that few had a salary exceeding £700 a year. There was a 1 to 9 chance against any of them becoming a chief, and many had children to educate. Consequently the service was a disgruntled one. He considered that general practitioners might do part-time work in the service, but he had inquired among practitioners in his division of the British Medical Association and only two had been willing to undertake the work, both of whom were newly established. He suggested that a census should be taken of members of the service.

Dr. W. G. WILLOUGHBY said it was unfair to lead junior members of the profession into a blind alley. He did not agree with the idea of a scale, but thought the maximum salary should be open to allow the best worker full prospects.

Sir THOMAS LEGGE said he spoke from the industrial aspect. He had hoped to hear something at the meeting of the Factories Bill, but the Local Government Act was evidently of more importance at the moment to the Society. He regretted that so much of the discussion had been concerned with the pay. In his experience the poorest paid generally worked best. As a Society they should attempt to get rid of their extreme sensitiveness; the slightest criticism of their work was apt to provoke a storm.

Dr. G. F. BUCHAN said that the work of the service was enormous, and extremely attractive to the worker entering it. The opportunities for research were considerable, and the only reason for discontent was the limitation of salary. He thought promotion should be arranged on the plan followed among the clergy, and not as at present, where the local assistant was usually promoted into the vacant senior office. He did not see how the general practitioner could be worked into the scheme, or what offices he could perform.

Dr. W. G. BOOTH said that if the minimum salary were fixed at £700 a year, he thought the authorities would pay it. He considered the Society should look ahead. Was it to become a State service? If so, now was the time to fix salaries on a suitable scale.

The PRESIDENT said that medical officers of health nowadays were purely administrative; they did not interfere with the welfare or tuberculosis staffs if the work was well done, and the same would apply to factories should they come under the control of the service. The members of the service were in no sense grasping; it was in the interests of the health of the general public that they appealed for reasonable conditions of work. As to being sensitive, no one could occupy a public health office for so much as a year if he had not the hide of a rhinoceros. Disregard of criticism was quickly acquired.

Dr. ANDREW BALFOUR said that the new London School of Hygiene hoped to supply "refresher" courses, and to help the workers in the public health service to keep abreast of advances in research.

MANCHESTER MEDICAL SOCIETY.

AT a meeting of this Society on Dec. 4th, 1929, with Dr. A. RAMSBOTTOM, the President, in the chair, a paper on

Sensitisation Associated with Eczema and Trade Dermatitis of the Eczematous Type

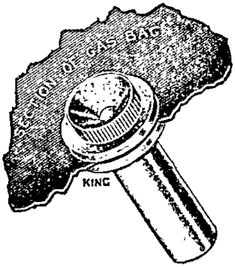
was read by Dr. WILLIAM DYSON. These two conditions, he said, were clinically and histologically indistinguishable. Their liability to relapse was well known, and if the attacks were prolonged or often repeated a general sensitisation of the whole skin might arise. When a sensitisation was established the skin would react to any external irritant. In Dr. Dyson's opinion the cause of this sensitised state must be looked for in some change which had taken place in the individual. He suggested that this change was brought about as the result of the absorption of the products of inflamed or damaged epithelium which set up a condition of hypersensitiveness—"an anaphylactic state." He showed that in non-discharging pruritic dermatitis a high blood-sugar was to be expected, whereas in cases which were discharging the blood-sugar content was lower, suggesting that when the products of inflamed epithelium were absorbed a high blood-sugar was to be expected, whereas when these products were being discharged on the surface the blood-sugar content was less. On the supposition that sensitisation was an anaphylactic state, he had treated 15 cases of eczema and eczematous trade dermatitis with injections of their own blood, with a view to producing and keeping them for a long period in an anti-anaphylactic state, and in this way desensitising the patient. In 10 out of the 15 cases the treatment had been successful in clearing up the dermatitis, and only one of these ten cases had relapsed up to date.

Dr. W. J. RUTHERFURD read a paper on Small-pox in Pre-Norman Britain.

New Inventions.

ETHYL CHLORIDE INHALER.

WHEN administering ethyl chloride one requires a special inhaler unless the "open method" is adopted. It has occurred to me that if a fitting could be incorporated in the usual dental N_2O bag the necessity for extra apparatus could be avoided. I have therefore devised a simple apparatus to this end, by adapting the spring ball valve of Looseley's inhaler to a flanged metal tube that can be fixed to any ordinary gas-bag, without taking up additional space. When attaching this fitting (shown by the illustration) all that is necessary is to punch a ⅜ inch hole in the bag, preferably near the stop-cock where the rubber is doubled. The advantages of this fitting are mostly obvious in juvenile dental patients; it is inexpensive, and can be fitted to any existing gas-bag.



Messrs. A. Charles King, Ltd., 34, Devonshire-street, London, W., are the makers.

GERALD MORIARTY, M.D. Edin.

Reviews and Notices of Books.

PRINCIPLES OF BACTERIOLOGY AND IMMUNITY.

By W. W. C. TOPLEY, M.A., M.D., M.Sc., F.R.C.P., Professor of Bacteriology and Immunology, University of London, London School of Hygiene and Tropical Medicine; and G. S. WILSON, M.D., M.R.C.P., D.P.H., Reader in Bacteriology and Immunology in the same School. London: Edward Arnold and Co. 1929. 2 vols. Pp. 1300. With 242 illustrations. 50*s*.

THIS book is one which we feel sure will receive a cordial welcome from all practising bacteriologists and teachers of this subject. The authors have for some years been engaged in teaching bacteriology, as a post-graduate subject, for the diplomas of the universities of Manchester and London, and the present work is the outcome of their experience, being based upon the course of study which they now give in the London School of Hygiene and Tropical Medicine.

The book consists of two volumes each of some 600 pages. The first of these is an up-to-date text-book of bacteriology in which the conventional arrangements are generally followed; whilst the second treats in detail of the reactions between the body and bacteria—i.e., infection and the immunity phenomena. Taking these volumes separately, for in effect they are almost distinct, we note that the first consists of two sections, in one of which historical, morphological, and physiological considerations are dealt with. No attempt has been made to set out cultural and tinctorial methods at any length, and in our opinion Prof. Topley and Dr. Wilson are wise in this bold exclusion, since there are already numerous special works on these subjects. The historical outline is an admirably concise and accurate review of the evolution of bacteriology, whilst the chapter upon physiology is admirably lucid and includes an honest attempt to correlate what is known of bacterial metabolism with current knowledge of enzyme action and other general biochemical phenomena. Bacterial variation is described clearly, but condensation has made the facts appear simpler than they really are. The systematic treatment of bacterial species, which occupies the second half of this volume, is orderly and convenient; the same group of properties being described seriatim for each organism. This arrangement will be much appreciated by students and makes for ease and rapidity of reference. The nomenclature used is that of Bergey, with inconsiderable modifications; the authors admit no great love for this terminology but adopt it (for want of better) as being at least a reasonable advance upon the irrational pre-war usage.

The second volume is also divided into two parts, of which the first deals with infection and resistance, and the second with the applications of bacteriology to medicine and hygiene. It really forms a separate text-book upon infection and immunity. Thus, whilst the actinomyces occupy Chapter XII. in Vol. I., the disease, actinomycosis, occupies Chapter LV. in Vol. II., and the same holds good for other organisms and the infective condition to which they give rise. It might be imagined that this arrangement, which is no doubt the outcome of experience in teaching bacteriology as a pure subject, would lead to considerable overlapping; and the impossibility of entirely preventing this is freely admitted. But so much care and judgment have been exercised in the segregation of material that we have sought in vain for serious evidence of this defect. In some places the line has obviously been difficult to draw. The serum reactions find themselves in Vol. I., whilst a consideration of animal immunity and the humoral antibodies is in the second volume. In general, there is a good deal to be said both for and against this arrangement, but the successful way in which Prof. Topley and Dr. Wilson have overcome its inherent disadvantages forms a strong argument for its use.

It is scarcely possible here to discuss more than a few sections of the book, but we note that adequate but not disproportionate consideration is given in Vol. II. to the special work of Topley and his associates upon experimental epidemiology and herd immunity. The laboratory diagnosis of enteric infections is considered in great detail, the authors pointing out that non-recognition of the diphasic character of the salmonellas invalidates the assumptions upon which Dreyer's standards were adopted, and, further, that there has been no general adoption in routine diagnostic practice of the contributions of Andrewes and White to our knowledge of antigenic structure; one consequence being that O agglutination is in general absent with "standard" formalinised suspensions. The "Widal" test, as recommended by the authors and devised to detect both H or O agglutinins for the common types of enteric infections, involves the use of no less than nine suspensions. This theoretically desirable complexity means that such tests, to give accurate and full information, can only be carried out in a well-equipped and well-staffed laboratory or, alternatively, that the clinical pathologist in smaller centres must become completely dependent upon the larger institutions for the supply of his reagents.

The authors' researches into the literature have evidently been both extensive and critical, and whilst they do not seem to have neglected any contributions of serious merit they have avoided the mere catalogue of other people's opinions—sometimes entirely contradictory—which is a common and unfortunate feature of many modern pathological and bacteriological books.

There is much in these volumes to commend and little to criticise. The material dealt with has been well digested and is summarised and presented in an orderly and easily assimilable form, and in far greater detail than in any English or American text-book of reasonable size with which we are acquainted. Most of the outstanding problems of bacteriology are courageously tackled; the issues are clearly and frankly set out and the authors' general conclusions are presented with a happy combination of dogmatism and judgment. The inquirer is rarely left in the air; usually he is presented with some sort of working hypothesis even if this is admittedly a temporary one. The book is a notable production and illustrates well the high level of bacteriological practice and teaching now attained in our universities.

EFFECTS OF MOISTURE ON CHEMICAL AND PHYSICAL CHANGES.

By J. W. SMITH, B.Sc., Ph.D. London: Longmans, Green and Co. 1929. Pp. 235. 15*s*.

LIFE is impossible without water, and yet the study of extreme dryness may be of great interest to the biochemist, since the catalytic effects of water can only be demonstrated by careful dehydration. This book is a summary of our present knowledge of the influence of traces of moisture on chemical and physical changes, and therefore deals principally with the "abnormal" behaviour of very dry substances. Many of the results described will surprise the purely medical reader, as also will the extraordinary precautions which are necessary in the doing. For example, everyone knows that iron will not rust in dry air, but the fact that potassium can be distilled unchanged in very dry oxygen is not so familiar. Indeed, the most striking characteristic of water as a catalyst is the very large number of reactions which it affects. Of more than a hundred which have so far been studied only a few have given negative results, and examples of every type of chemical reaction have been shown to be stopped, or at least retarded, by thorough drying. In the case of physical properties the general nature of the effect is even better established since *all* the liquids and solids so far investigated have shown some change in physical properties after intense desiccation. The work of H. H. Baker is a good example of the care needed to obtain positive results.

He sealed up a number of liquids in glass vessels with phosphorus pentoxide and left them for eight years from 1913–21. At the end of this time he found that the boiling points had risen considerably; for example, alcohol boiled at 138° C. instead of at 78·5°C.

A very large number of theories have been put forward to explain aqueous catalysis. Those best known in biochemistry assume the formation of an intermediate compound and have been used especially in the case of biological oxidations; as an example we may recall Traube's theory, in which hydrogen peroxide was the compound selected. Such theories are justly criticised by the author on the ground that they are not of sufficiently general application. More space is devoted to Smits's theory, which is not open to this objection, and which is supported by considerable experimental evidence. Smits assumes that a substance exists in two or more forms in equilibrium with each other. Only one of these is chemically active, and the equilibrium is "frozen" or actually displaced in the direction of the inactive form by the removal of water. The different forms have different physical properties, and can be separated by fractional distillation of the very dry substance, a feat which has actually been accomplished in the case of sulphur trioxide. Smits's theory also appears to supply the best explanation of the way in which extremely small quantities of water may act, since the fraction of the total molecules existing in the active state is about 10^{-10} and the fraction of water molecules necessary for the activation of a completely inactive system is of the same order. An interesting chapter is included on the influence of traces of other catalysts on the physical properties of liquids. When liquids are sealed up with solid catalysts such as platinum black or charcoal, changes in the vapour pressure, surface tension, and density have been demonstrated. These are explained in a similar fashion to the above, a shift in the inner equilibrium between the smaller and larger molecules being assumed.

The book is well written and the subject is ably presented. The historical introduction and the diagrams in the text are features of special value, and the author is to be commended for his refusal to sacrifice accuracy to simplicity. He is careful to avoid making dogmatic statements, and succeeds in giving an unbiased account of the many controversies which have arisen; if the result is slightly confusing in places this is to be attributed to the unsettled state of the subject, which provides ample justification for his impartial attitude. The book will be read with considerable interest by biochemists, if only because it reveals how little we know of catalysis in general, and of the catalytic action of water in particular. At a time when the study of the action of water on pure substances has only just begun, we should not be surprised at the difficulty of assessing its rôle in the living body.

NOSE, THROAT, AND EAR.

A Manual of Diseases of the Nose, Throat, and Ear. Sixth edition. By E. B. GLEASON, M.D., LL.D., Professor of Otology, Medico-Chirurgical College, University of Pennsylvania London and Philadelphia. W. B. Saunders Company. 1929. Pp. 617. 21s.

THIS well-known manual was first publised in 1907. In these two and twenty years there has been much progress in the science of otolaryngology. Though the book has become somewhat large with each edition, it has nevertheless suffered a little from compression; the print is rather close, and the illustrations, especially those of pathological subjects, too small. A more rigorous exclusion of obsolete matter, such as the removal of septal spurs with the saw, would help to solve the difficulty of lack of space. Misprints and errors of grammar are too frequent.

The book is full of information derived from a ripe experience and well deserves its popularity.

TROPICAL MEDICINE.

Krankheiten und Hygiene der Warmen Länder. A Practical Text-book. Third edition. By Profs. Drs. REINHOLD RUGE, PETER MÜHLENS, and MAX ZUR VERTH. Leipzig; Georg Thieme. 1930. Pp. 496. M.39.60.

THE general format of this out-standing text-book remains the same, and although a large amount of additional information has been compressed within its bulk, mainly by the liberal adoption of small type and slightly larger pagination, the total increase is but five pages over the original. It differs from English text-books on tropical diseases in that much space is devoted to the consideration of the usual subjects of tropical climate, acclimatisation, nutrition, and general adaptability to tropical conditions. A good deal of this information is based upon somewhat debatable data and much is the outcome of ordinary common sense. The metabolism of the human body is necessarily disturbed by exposure to tropical conditions, but the adaptability of the human organism is so great that much more detailed biochemical work will have to be undertaken before these variations can be placed upon a strictly scientific basis. We may note amongst other minor changes a small section devoted to surgery in the tropics. The advisability of this inclusion is questionable, for a large subject is treated in an abbreviated and rather stilted manner. The number of excellent coloured plates remains the same though the text-figures are increased to the number of 40. A whole plate is devoted to microphotographic reproductions of malaria parasites (from Kolle and Wassermann), which, however admirable, do not by any means approach in teaching value the black-and-white drawings or coloured figures. The production of this edition is a testimony to the continued vitality of tropical medicine in Germany.

Hookworm Disease: Its Distribution, Biology, Epidemiology, Pathology, Diagnosis, Treatment, and Control. By ASA C. CHANDLER, M.Sc., Ph.D., Professor of Biology, Rice Institute, Houston, Texas; recently Officer-in-Charge, Hookworm Research Laboratory, School of Tropical Medicine and Hygiene, Calcutta, India. London: Macmillan and Co., Ltd. 1929. Pp. 494. 21s.

HOOKWORM disease is one of the most widespread and devastating of all ills. Its literature is so scattered that one who undertakes to compress it into reasonable compass deserves gratitude. Dr. Asa Chandler, who is an authority of international standing, has done the work admirably well. Our knowledge of the biology and morphology of *Ancylostoma duodenale* is still based upon Loos's exhaustive work published in 1911; but since that time great advances, thanks mostly to the energies of the Rockefeller International Health Board, have been made in the direction of prevention and treatment, and it is from this aspect of the subject that the practical medical man will derive much assistance from a study of Dr. Chandler's monograph. According to Dr. Chandler, thymol and beta-naphthol treatment have been definitely replaced in hookworm therapy by oil of chenopodium and carbon tetrachloride. Oil of chenopodium, he states, has advantages over the two first-named drugs in its safety and simplicity of administration, and also in its further advantage of being effective against ascarids and other intestinal nematodes. Carbon tetrachloride, in his view, outscores oil of chenopodium in about the same degree that chenopodium outscores thymol. In the vast majority of patients he believes it to be quite harmless, produces few or no unpleasant symptoms, and can usually be taken without interference with the day's work. Its cost is so low as to be negligible. Dr. Chandler holds that the combination of carbon tetrachloride and oil of chenopodium, each in reduced dosage, provides an almost ideal anthelminthic.

THE QUEEN CHARLOTTE'S PRACTICE OF OBSTETRICS.

Second edition. By J. BRIGHT BANISTER, M.D., F.R.C.S., ALECK W. BOURNE, M.B., F.R.C.S., TREVOR B. DAVIES, M.D., F.R.C.S., L. CARNAC RIVETT, M.C., F.R.C.S., L. G. PHILLIPS, M.S., F.R.C.S., and C. S. LANE-ROBERTS, M.S., F.R.C.S. London: J. and A. Churchill. 1929. Pp. 635. 18*s*.

THE second edition of "The Queen Charlotte's Practice of Obstetrics" differs little from the first. Such small errors, misprints, and omissions as creep into new books, in spite of the most careful proof-reading, have been corrected, but little new matter has been added. The authors do not claim that the work is more than an exposition of the practice of a famous maternity hospital, teaching which may or may not be generally accepted. This fact disarms criticism, which in any case would be difficult to justify since the authors have produced one of the most practical works on obstetrics in the English language. There is one point to which attention might be drawn. Throughout the book the term "disproportion," which is now so largely adopted in place of such terms as "minor degree of contracted pelvis," is hardly mentioned. Surely the majority of "tight fits" are better regarded and dealt from this point of view. In the same connexion it is to be regretted that the importance of moulding of the fœtal head does not receive greater prominence.

The first edition achieved immediate and well-deserved popularity which is likely to continue.

MAN'S PLACE AMONG THE MAMMALS.

By F. WOOD JONES, F.R.S., Professor of Physical Anthropology, University of Hawaii. London: Edward Arnold and Co. 1929. Pp. 372. 21*s*.

WHEN the conception of evolution was first sprung upon a horrified Anglo-Teutonic world by the work of Darwin and Haeckel, the way had already been prepared by several zoologists who had recognised the varying degrees of differentiation in the animal world and had arranged all known species in scales of increasing complexity. The idea of evolution did little more than give a shake to these rigid schemes and turn the "échelle des êtres" into a moving stairway. At first, therefore, the idea of evolution followed strictly along the lines of this classification, and it was assumed implicitly that the amœba had evolved to man through all the other known animals, and also through a number of intermediate stages which have not survived. As soon as the idea of evolution had been accepted without the prejudice which it first evoked, it became plain to thoughtful biologists that the rigid and relatively simple process described by Haeckel could not represent the truth, and the conception of evolution has been steadily changing ever since from that of a stairway to that of a tree. The tree has many collateral branches, and most of the animals living on the earth to-day are representatives of the extreme tips of twigs, rather than occupants of places on the stem from which other twigs arise; they are, in fact, cousins—often several times removed—and not ancestors or descendants of each other.

So much is admitted by most, but when it comes to applying the principle to man and his nearest relatives, there is still some fairly acute difference of opinion. Prof. Wood Jones stands in the front rank of those who apply this idea whole-heartedly and declare that the problem of man's ancestry is to be studied not among the apes and monkeys, but among simple arboreal mammals. As a result of following up this line of thought he has come to the conclusion that man is structurally a very primitive mammal, much nearer the common ancestors of the mammals than most of the animals we know to-day, but distinguished by the development of his brain and hand and the changes incident on the assumption of the upright position. These views have been put forward in two previous publications—"Arboreal Man" (1916), and "The Problem of Man's Ancestry" (1918)—both of them somewhat hampered by the difficulties of publication and research during the war, and both of them in the form of published lectures. Now Prof. Wood Jones has supported these by the volume under review, which goes thoroughly into all the evidence for his theory and reviews the evolution of biological thought and the anatomical characteristics of the primates in relation to those of man. His conclusions, summarised, are: that the members of the proto-human stock were small, active, agile animals, with legs longer than their arms; that they were already erect and prepared for terrestial life, and that they possessed enlarged crania, small jaws, and moderately large eyes. He vividly contests the picture of the slouching hairy brute with elongated arms, lumbering into a stage of partial uprightness, which is usually drawn as that of the ancestor of man. Like all Prof. Wood Jones's books, this is lucidly and attractively written and illustrated with charming line-drawings of his own and excellent photographs of monkeys and apes from the London Zoo. As he says in his preface, the objections to his thesis are of two kinds: first that it is ridiculous and unwarranted, and alternatively, that it is so generally admitted as to stand in no need of exposition. Whichever point of view the expert may take, he will still need to read this book, and to the ignorant, who do not profess to know all there is to be known about evolution, it will certainly be a delightful review of the ever-absorbing problem of their own ancestry.

RECENT WORK ON COLPORRHAPHY, RHEUMATISM, AND COLI BACILLURIA.

By E. HESKETH ROBERTS, F.R.C.S. Ed., M.B., B.S. Lond., Gynæcological Surgeon, St. John's Hospital, Lewisham. London: H. K. Lewis and Co., Ltd. 1929. Pp. 28. 3*s*.

IN this short monograph the author gives a careful account of the technique he employs for the operations of anterior colporrhaphy and posterior colpoperineorrhaphy. He describes a new layer of the visceral pelvic fascia which runs down the lateral aspects of the rectum and vagina. Recurrence of symptoms is liable to occur after these operations, and the author puts forward his views on the significance of chronic rheumatism and colon bacilluria as ætiological factors.

OUTLINES OF DENTAL SCIENCE.

Vol. XII., *Dental Local Anæsthesia*. By JOHN JAMES, L.D.S., Lecturer in Operative Dental Surgery, King's College Hospital Dental School. Edinburgh: E. and S. Livingstone. 1929. Pp. 127. 7*s*. 6*d*.

THIS is a straightforward account, suitable for senior students or junior practitioners, of the elements of local anasthesia as applied to dental surgery. The book is essentially practical and obviously written by one who has had considerable clinical experience. Mr. James favours cocaine in preference to novocain. He holds the toxicity of cocaine to be negligible and has no fear of engendering drug addiction by its use. Somewhat illogically he bases his preference for novocain in regional injections on its lesser toxicity. We know that many dentists use cocaine as a routine anæsthetic and that accidents are few, but in a book primarily intended for students or junior practitioners such advice may be dangerous. The technique of local anæsthesia is clearly and adequately described. The chapter on novocain dermatitis should prove useful, but for the most part the chapters on complications and contra-indications are rather too brief, since the possible complications of local anæsthesia are numerous and may be serious. Similarly, the contra-indications to the use of a local anæsthetic are of definite importance, and should receive full consideration in a text-book on local anæsthesia.

THE LANCET.

LONDON: SATURDAY, JANUARY 4, 1930.

THE COMING OF RADIOLOGY.

A MODEL on view *at the Charing Cross District* Railway Station takes the lid off the underground system and enables the passenger to visualise the working of the whole system of tubes with their controls and safety devices. RONTGEN's discovery did much the same for the human alimentary canal although he did not live to see to what extent it was to revolutionise medical practice; and indeed the revolution is by no means yet complete. For the first 15 years the radiologist was relying entirely on the varying atomic weights of the chemical components of the body to differentiate them on the screen; an X ray picture then showed little more than the skeleton within the soft parts. The introduction of the opaque meal about the year 1906 opened up the possibility of examining the working of all the tubular systems in the body; bismuth and barium have revealed the alimentary canal, iodine has clearly shown lesions in the genito-urinary system, the bronchi, and the spinal canal, and has made a start with the circulating blood, and what the future will bring forth only a brave prophet would say. In a paper read not long ago before the Society of Radiographers, Dr. A. E. BARCLAY remarked that the surface markings of the abdominal contents as they are now charted in students' text-books are hopelessly wrong. The living conception of the position and movements of the viscera made possible by the use of the opaque meal has shown that the shape of the viscera depends on the tonic action of the muscles which so largely compose them, that their shape varies from person to person and indeed in the same person from day to day or hour to hour. Thus the lower border of the shadow of an apparently normal stomach may be seen to drop perhaps 3 or 4 inches because of the sudden banging of a door or by the advent of nausea or giddiness. The radiologist, said Dr. BARCLAY, was inevitably struck by a lack of uniformity in the relation of the extent of the disease to the symptoms to which it gives rise. Radiology had wiped out quite a large number of text-book diseases of the stomach, each with its own set of symptoms, and only two common chronic diseases of that organ remained—namely, ulceration and cancer. For the rest, the stomach was the spokesman for the other abdominal viscera; they were apt to refer their grievances to the stomach for expression, and with the help of bismuth or barium (the Manchester Royal Infirmary alone uses about three-quarters of a ton of barium sulphate in the year) such vague complaints as nervous dyspepsia and gastritis were now referred to their place of origin in the gall-bladder, the duodenum, or elsewhere.

This *revolution in our knowledge of visceral* function has not only required steady devotion on the part of its adherents but has involved an outlay of money in apparatus such as no other branch of medicine involves. The equipment of the radiologist is expensive to start with and it rapidly depreciates in value as new methods are worked out. For this reason, although radiology in private hands holds a bright prospect (Dr. G. B. BATTEN estimates that a population of 50,000 is sufficient to maintain a whole-time radiologist), it may be desirable, as Dr. FFRANGCON ROBERTS suggested in our own columns three weeks ago, to centralise the apparatus. He has gained the impression that radiologists in this country have no desire to burden themselves with their own apparatus if they can have the use of installations at hospitals or central institutes. In Germany it seems the equipment and organisation for radiology have made enormous strides; the municipal *hospital at Frankfort-on-Maine has an institute* which has cost £2 14*s.* per cubic metre, an expense which was defrayed partly by the State and partly from the central pool of sickness insurance. Dr. ROBERTS points out quite fairly that provision for radiological diagnosis and treatment under the Insurance Acts would go far to solve the needs of radiology in this country, while the claim for State support has been strengthened by the Local Government Act of 1929 which requires voluntary hospitals to provide X ray facilities for other hospitals in the area.

The fruits of radiology will not be garnered until the practitioner realises its value to him in the daily treatment of his patients, and until the eyes of patients themselves are opened. It may not be possible for every general consultant to have an X ray installation in his consulting-room and to regard no clinical examination as complete without a view of the thoracic and abdominal organs on the fluorescent screen. As soon as he has to rely on a specialist the trouble begins; dissatisfaction with the X ray operator has been often enough expressed. One of the discussions at the recent Radiological Congress gave the radiologist the opportunity of pointing out the many types of unsatisfactory clinician met with at the present time, ranging from those who regard radiology as a joke or as an unimportant aid to diagnosis, to those who wish to interpret their own radiograms or to have them interpreted without reference to the patient's symptoms. There must be an increasingly sharp distinction, as a correspondent remarked in a letter to our columns on Nov. 30th last, between those who know what radiology will do and those who can actually take the films; but the practitioner, it seems, has little means of learning what it will do and therefore does not seek its aid. How this state of affairs is to be rectified engaged a good deal of the attention of the Congress, and the British Institute of Radiology may well have a part to play in organising post-graduate classes on the place which electrical methods and especially radiology may play in medicine. The National Insurance Fund might help by providing panel practitioners with facilities at least for learning what radiology will do, and there is a place for the endowment of chairs and lectureships in radiology. We have no reason to doubt the correctness of Dr. ROBERTS's impression that the special claims of radiology for State support have never been presented, or at all events presented adequately.

◆

DOCTORS AND LOCAL AUTHORITIES.

THE question how far medical practitioners are *disqualified from membership of local authorities* requires fresh consideration in view of the impending changes caused by the new Local Government Act. The Minister of Health has sent Dr. VERNON DAVIES, M.P., an important memorandum on the subject, not only explaining what he understands to be the law, but also hinting at future changes on a matter dealt with in the Final Report[1] of the Royal Commission on Local Government, which has just been issued.

The broad principle is clear. Anybody who has a contract, or is interested in a contract, with a local authority is disqualified from membership of that body. As the Minister points out, this is a general rule, applicable to employees of all kinds, solicitors, architects, and engineers, for instance, as well as doctors. One of the consequences of the new Act is to transfer numbers of officers and employees from one local authority to another. A medical practitioner may thus find himself the employee of a local authority of which he is a member; if so, he is automatically disqualified from further membership. In one respect the situation may be simplified under the new Act, for part-time medical employment will, in some degree, be giving way to whole-time employment. It needs no legal knowledge to appreciate that a whole-time servant cannot be simultaneously a master; obviously he will be debarred from membership of the body he serves. In other directions matters are not so easy. In the eye of the law the elements of a contract are present whenever a doctor does any professional work for which he receives a fee from a local authority. Parliament has recognised and remedied this difficulty in certain well-known cases where the work is of a minor or routine nature. It is specially enacted, for instance, that a doctor sending a certificate of an infectious disease (and receiving a fee therefor) shall not be disqualified from membership of the local body on that account. Similarly, there is a rule that a doctor attending a confinement on demand from a midwife, and consequently receiving a fee under the Midwives Act of 1918, is not disqualified. This ruling is not directly statutory, but is based on the technical subtlety that the doctor is not taking a fee under a contract of employment with the local authority, but that the authority is fulfilling a statutory obligation in paying him a fee for work done in special conditions contemplated by statute. Outside these specific exemptions two important classes of cases are mentioned in the Minister's memorandum. On the one hand, there are the doctors who work under a contract for occasional service—e.g., attendance at a maternity and child welfare centre, with remuneration at specified fees. The Minister states definitely that these practitioners are disqualified by the contract though it seems that the Royal Commission's Report looks for the removal of the bar. On the other hand, there is the class of cases where a local authority makes payments to a hospital with the result that a physician or surgeon working at the hospital receives some part of the payment. In these cases, says the Minister, disqualification depends upon the particular facts—in other words, the medical practitioner is left to act at his own risk, and to find out his legal liabilities in a court of law.

The situation can hardly be deemed satisfactory. The local administration of health services is not the monopoly of the medical profession. Equally it is not a form of public work to which the medical profession should be prevented from making any independent contribution whatever. Teachers, it is understood, are represented in the deliberations upon local education schemes. There seems no sense in excluding the doctor from deliberations upon health matters merely because he may find himself performing some individual service for which the local authority may pay him a fee, or because he is on the rota for duty at a maternity and child welfare centre, or is consultant to some institution rendering public assistance. The views of the Royal Commission demand serious attention. The Commissioners, it may be surmised, do not think it an advantage, either to the medical profession or to the country, that members of the profession should be barred by law from the opportunity of participating in public work as members of local bodies. Insistence upon disinterestedness is proper and in accordance with our best traditions; but where interest intervenes casually and as it were by accident, insistence need not be a fetich. A High Court judge is not thought incapable of trying an action against a railway company because he happens to be a shareholder. He mentions the fact and inquires if the parties object to his jurisdiction on that account; no objection is ever taken. If similar confidence were reposed in a medical member of a county or borough council nobody would assume that it would be misplaced. The medical member would naturally not take part in discussions or decisions affecting his own fees or professional services if any such question ever arose. In all else he should be free to coöperate with his fellow-councillors. The fact that he knows what he is talking about should not necessarily be a disqualification.

◆

INDIA AND THE G.M.C.

FOR some time past it has been apparent that the relations of the Indian universities with the General Medical Council were becoming increasingly strained and that recognition in the United Kingdom of their medical degrees was hanging in the balance. At the November session of the Council Sir DONALD MACALISTER made it clear that matters had reached a crisis; in his Presidential address he gave a brief summary of the course which the Council had taken since 1922 when it was first found necessary to draw attention to certain deficiencies in Indian methods of training and examination. It has never been denied that excellent work has been put into the various medical colleges in the past, and originally, in many respects, their facilities compared favourably with those of similar institutions elsewhere. This was made evident by the high honours which some of their students obtained periodically in British examinations. But, as at home, conditions changed for the worse during and after the war, owing to the overcrowding which was inevitable at that time, and it was a matter of common knowledge that schools with twice the normal number of students were working with facilities which had been little if at all expanded since the war. The deficiency which first attracted attention was in midwifery, a subject in which it has always been difficult to arrange for practical instruction in India, but it has since been shown that clinical material for other subjects was inadequate during this period.

When these deficiencies came to their notice the General Medical Council very reasonably drew attention to them, pointing out that in its capacity of guardian for the British public it could not overlook obvious shortcomings of this character, if Indian graduates were to be allowed to practise in the United Kingdom. The line taken by the Council, as Sir DONALD has stated, was that India should herself give some guarantee of uniformity of standards, the best means to this end being the creation of an All-India Medical Council, which would be responsible for the regulation of medical education and registration in India, in much the same way as the General Medical Council is responsible at home. Provincial medical councils already exist, and these would presumably continue in some form, but it was evidently thought that under present conditions they could not provide adequate assurance of the maintenance of uniform standards. The Council recognised, however, that the establishment of a central body would take time, and in order to allow for a period of reconstruction it asked that an inspecting officer should be appointed, to keep the Council informed of the condition of the various schools and the standard of examinations. The proposal was accepted, and an inspector, appointed by the Government of India, for some time kept the Council in touch with the schools. Incidentally, with a certain amount of discussion—and sometimes it must be confessed with some friction—various improvements designed to bring the Indian schools more or less into line with the revised British curriculum were introduced, and with one or two exceptions recognition of the Indian degrees for practice in the United Kingdom was maintained, and extended from year to year, pending a more permanent solution of the difficulties by the constitution of an All-India Council. The negotiations can be followed in detail in the minutes of the G.M.C.; suffice it here to set out the way in which they finally broke down. Regular inspections by a single approved official having lapsed, the Council has asked to have them reintroduced, and has further pressed for the setting up of an All-India Council. Both provincial and central governments, recognising the gravity of the situation, agreed to the reappointment of an inspector, and the same officer who had carried out the duties previously, and whose experience made him the one man suitable, was kept in readiness for the post. Arrangements for introducing an All-India Medical Council Bill, which had been for some time under consideration, were completed, and a draft was brought to the notice of the authorities concerned. What is the result? The proposal for the appointment of a Government commissioner of medical qualifications and standards evoked strong criticism from the nationalist members in the Legislative Assembly, and it was found necessary to postpone its consideration to a later session. The preliminary negotiations for the formation of an All-India Council got no further. The captious nature of some of the arguments against the appointment of an inspector may be judged from the fact that one speaker objected on the score that the officer proposed belonged to the Indian Medical Service, while another—one of the most prominent Hindu leaders—spoke of the disrespect which such a proposal involved to the Indian universities. He would rather, he said, close the universities than have them submit to such an indignity, and he would welcome the day when British registration of Indian degrees was considered of no value. There was also a good deal of wild talk of medical dictators and the tyranny of the British—i.e., the General Medical Council.

---

[1] H.M. Stationery Office, Cmd. 3436, 1929, pp. 169, 3s., see p. 157.

The issues at stake are undoubtedly grave, involving, if only Indian educational and political leaders would realise it, not merely the recognition of Indian degrees in Great Britain, but their standing everywhere outside India also. The G.M.C. has exercised patience to the utmost limits; in spite of frequent misrepresentations it has been the best of friends to the provincial councils in India, which were founded largely on its example and advice. Time and again Sir DONALD MACALISTER has made it clear that the Council is not concerned with the standard deemed sufficient for practice in India, but only with that which it is required by law to enforce for medical practice at home, and it is easy to imagine that nothing would please the Council better than to divest itself of all responsibility for Indian affairs. The matter, however, is of such deep concern to India that we trust the Council will continue to exercise the patience and forbearance it has shown so abundantly in the past. The more sober sections of Indian opinion will no doubt realise the importance of a link which the extremists are so eager to cut. They will see that recognition once lost may be very difficult to regain, and we may hope that even at the eleventh hour some acceptable plan may be arrived at. The creation of an All-India Medical Council cannot injure national susceptibilities, it will increase national prestige; while the appointment of an inspecting officer is a temporary expedient to fill in the interval before it is appointed. But the time for action on either side is short if, as now appears, recognition is not to be extended beyond February in the absence of the required reports. It would indeed be lamentable if all the efforts of administrative officers, and other people of goodwill both in England and India, were to be rendered null and void by a few words spoken in the heated atmosphere of the Legislative Assembly.

Annotations.

"Ne quid nimis."

NEW YEAR HONOURS.

THE following is the list of New Year Honours as far as they directly relate to the medical profession. It was issued on the last evening of the old year. No medical names are to be found among the new peers or baronets.

G.C.B.

Surgeon Rear-Admiral Robert William Basil Hall.

C.B. (Military Division).

Major-General David Harvey, C.M.G., M.D., K.H.S. (late Royal Army Medical Corps), Director of Pathology, the War Office.

Colonel Arthur Brownfield Fry, C.I.E., D.S.O., M.D., Indian Medical Service, Assistant Director of Medical Services, Presidency and Assam District, India.

K.C.M.G.

Sir James Crawford Maxwell, M.D., K.B.E., Governor and Commander-in-Chief of Northern Rhodesia.

Lieut.-Colonel Andrew Balfour, LL.D., M.D., C.B., C.M.G., Member of the Colonial Advisory Medical and Sanitary Committee, Director of the London School of Hygiene and Tropical Medicine.

C.I.E.

Lieut.-Colonel Walter Valentine Coppinger, D.S.O., M.D., F.R.C.S.I., I.M.S., Inspector-General of Civil Hospitals, Central Provinces.

Lieut.-Colonel Arthur Francis Hamilton, M.B., F.R.C.S., I.M.S., Professor of Midwifery, Grant Medical College, Bombay.

K.C.V.O.

Russell Facey Wilkinson.

C.V.O.

Sir George Washington Badgerow, C.M.G., M.D., F.R.C.S.

Herbert Stanley French, C.B.E., M.D.

G.B.E. (Military Division).

Surgeon Commander William Innes Gerrard, M.B., D.P.H. M.R.C.P., R.N.

K.B.E. (Civil Division).

The Honourable Stanley Seymour Argyle, M.B., lately Chief Secretary and Minister of Public Health, State of Victoria.

O.B.E. (Civil Division).

William Alfred Stedwell Lamborn, M.R.C.S., L.R.C.P., Medical Entomologist, Nyasaland Protectorate.

Harold Armstrong Crouch, M.C., Medical Inspector, Upper Nile Province, Sudan.

Charles Johnston Smith, M.B., Senior Surgeon, Singapore.

M.B.E. (Civil Division).

John Young McFadyen, M.D., Magistrate and Medical Officer, Anguilla Island, Presidency of Saint Christopher and Nevis.

Knight Bachelor.

Prof. Temistocle Zammit, C.M.G., M.D., D.Litt., Curator of the Museum, Malta.

Kaiser-i-Hind Medal.

Miss Mary Longmire, M.B.

The following names will be recognised with pleasure in the list, as their owners in different capacities have worked in relation to medicine in one aspect or another.

Sir Gregory Foster, late Provost of University College, London, has been created a baronet. Mr. L. L. Cohen, hon. sec. to King Edward's Hospital Fund for London, receives the *K.C.V.O.* Miss Gertrude Tuckwell, a member of the Women's Central Committee on Women's Training and Employment, receives the C.H. Major-General William Samuel Anthony, C.M.G., Director-General, Army Veterinary Services, is created C.B. Prof. J. S. S. Brain, professor of chemistry at the R.N. College, Greenwich, receives the C.B.E., and Mr. E. S. Russell, D.Sc., of the Ministry of Agriculture and Fisheries, receives the O.B.E. The M.B.E. has been conferred upon Miss Elsie Hughes, secretary to Lord Dawson of Penn, for services rendered during His Majesty's recent illness, and the same distinction has been conferred upon Mr. D. H. J. Nicholas, in charge of the Government House Dispensary, Madras.

The O.B.E. (Civil Division) has been conferred upon, Miss Helen Grace Palin, principal matron, Ministry of Pensions Nursing Service, and Miss Lily Richards, matron, Royal Westminster Ophthalmic Hospital, while Miss Ethel Harrison, superintendent of the Northrup McMillan Nurses' Institute, Kenya Colony receives the M.B.E.

The following names among the nursing profession are included :—

Royal Red Cross 1st Class.—Superintending Sister Nita Courtice.

Superintending Sister Marguerite M. Abraham.

Royal Red Cross 2nd Class.— Nursing Sister Leonora C. Hooper.

Nursing Sister Alice M. Shrewsbury.

THE CHANGES IN THE HOSPITAL SYSTEM.

JANUARY will be an important month in relation to the arrangements, often difficult and complicated, for the taking over, under the new Local Government Act, by county councils and the town councils of county boroughs, of institutions hitherto belonging to poor-law authorities. In self-contained areas the operation will be simple enough ; the complications come in when the areas of these institutions are not wholly comprised within one county or county borough. When this happens the councils affected, which may be more than two, will have to come to an agreement. A fair number of such agreements have been reached, but many are still outstanding, and the sands are running out. If these adjustments are not made by the end of the present month they will be made by the Minister of Health, whose Order might conceivably take a form not altogether pleasing to one or other of the authorities concerned. The Ministry of Health has laid stress upon the obvious desirability and convenience of the ownership of transferred institutions being vested in one council, and it is here that friction seems most likely to arise. Happily, goodwill appears to be in the ascendant, and we may therefore hope that troublesome details will get themselves settled without an aftermath of local jealousy.

Good progress appears to have been made in the constitution of the Public Assistance Committee upon which so much hard work will fall. In a number of instances, however, councils have taken the view, which they are perfectly entitled to take, and act upon, that only elected representatives of the ratepayers ought to serve on these bodies. Nevertheless this view will probably be found, by experience, to be short-sighted. By no means every elected councillor has been a guardian, and intimate knowledge of poor-law work on the part of those who will in future have to administer it is surely essential. Education committees are almost invariably "stiffened" by the coöperation of experts, and the power to coöpt is one of the most useful of the liberties accorded by the Act. Some complaints are also made of the insufficient representation of women on the committees. Women long ago became expert guardians, and there would seem to be wide scope for their help, also on the hospital side of public assistance. Upon certain subcommittees they are bound to be placed, but it is desirable that they should have a voice in that shaping of general policy which will be the work of the main body. It is hardly to be expected that a great new system, some of the implications of which are as yet obscure, should "shake down" at once. Experience, especially in the vitally important matter of coöperation between the public assistance hospitals and the voluntary hospitals, will be gained gradually, but meanwhile, so far as a general survey of the field is possible at this juncture, there appears to be an entire absence on the part of the county and town councils of any desire to interfere with the control of the voluntary hospitals.

The latter are, indeed, in so strong a position that there seems to be little ground for the fears that have sometimes been expressed, that they might be swallowed up. The simple fact that they are entitled to be consulted upon developments proposed by the councils, but are not called upon to consult the councils upon their own development, should be an almost complete safeguard. It is to be hoped, however, that there will be no mere standing upon dignity, no insistence upon the letter of the law in this highly important matter. The whole future of the new hospital system will depend upon constant good understanding and systematic well lubricated coöperation between the voluntary hospitals and those administered by public authorities. Not otherwise will it be possible to derive the fullest advantage from a change which aims at coördination and interchange, although not at technical fusion. Any general lack of understanding would have deplorable results, not the least deplorable of which would inevitably be a large degree of that bureaucratic interference which would be the worst of menaces to the voluntary system.

POSTURE IN HEALTH AND DISEASE.

SOME of the principles which govern the actions of the joints and muscular systems of the body were expounded by Miss M. Forrester-Brown in an address delivered to the London Association of the Medical Women's Federation on Dec. 16th. She held that these were not well understood either by general practitioners or by medical gymnasts. It was not generally realised that the normal spinal column is not equally mobile in all its joints. X rays show that extensor movements occur chiefly in the lumbar and cervical regions, and that there is a fixed kyphos in the thoracic region with its maximum at the seventh vertebra. Back-bending exercises, she said, increase rather than reduce this kyphos, and only under pathological conditions or in acrobats can it be reduced to lordosis. Other useful observations made by the lecturer are the following: The number and shape of the vertebræ exhibit considerable variation within normal limits. In the lumbar region four vertebræ may be present in an individual of stocky build, and five deep vertebræ are commonly found in slender, long-backed subjects, who tend to become visceroptotic and are always unsuited to heavy physical work. Ill-health may often be prevented by the choice of work to which the individual's physical type is best adapted. Muscles are more important than ligaments in affording support to joints. The tone of muscles depends on an intact reflex arc, and is diminished by fatigue in the central nervous system, and not by fatigue in individual or groups of muscles.

The effects of emotion on posture are illustrated by the typical attitudes assigned to fear, deceit, courage, and triumph, and, according to Miss Forrester-Brown, the effects on a child's temperament of treating faults in posture are often striking. The slouching child is often a sulky child. When judicious use of a long mirror makes the child realise the unsightliness of her posture, he or she can often be stimulated to take an interest in the treatment; it is when the patient coöperates with enthusiasm that the best results can be obtained. The attitude of the spine depends on the tone of the vertebral and abdominal muscles and on the tilt of the pelvis. The position of the head is relatively unimportant in connexion with good posture, for the reflex motor system is at peace provided the eyes are horizontal. That this effect can easily be achieved with a faultily held spine is evident in many tuberculous lesions of the spine where gross deformities are present. Good posture depends chiefly on good balance, and in maintaining this the spinal and abdominal muscles are of equal importance; factors such as warm air, tonsillar infection, and chronic constipation, which lower their tone, are responsible for bad posture in many children. The child living in a civilised community certainly suffers in several ways by being deprived of the stimulus of cold air and sunshine on the body, and the provision of these stimuli is an important factor in treatment.

The treatment of faulty postures, said Miss Forrester-Brown, are rest, fresh air, massage, and exercises, with correct breathing as an important adjunct. Mobility rather than depth of chest should be aimed at; the well-developed puffed out chest is not the ideal inspiratory position. When inspiration is carried out with both arms raised the muscles attaching the arms to the chest wall are shortened, the play of the ribs inhibited, and movements of the diaphragm diminished. Since diaphragmatic respiration represents a larger volume of air than thoracic respiration, so-called "abdominal breathing" should be taught to children in the recumbent position, and the shoulder-shrugging and leg-bending exercises should also be done in this attitude. The value of recumbency to the growing child is not nowadays generally appreciated. The Victorian principle of resting on a backboard was, in Miss Forrester-Brown's view, a sound one, and the teaching of deportment should be advocated. The country dancing now popular makes for a sense of rhythm, but does not inculcate balance, control of movements, and grace, as did training in the old court dances. Faulty sitting postures are common in school-children, and result in crowding of the ribs and sagging of the abdomen. Sitting in a straight-backed chair causes less fatigue if a small pillow is placed in the small of the back to support the natural lumbar lordosis. Such a pillow should be used also during operations in the Trendelenburg position. Its support of the sacro-iliac joint should prevent the post-operative pain in the leg which is caused by pressure on the nerves as they pass through the foramina.

CAUSES OF BALDNESS.

THE problem of common baldness is still more or less unsolved, and in its treatment we have made scarcely any progress of importance since Unna attributed the condition to infection by the organisms of seborrhœa. This explanation is evidently not the whole story; protracted and conscientious application of sulphur, which remains our most potent remedy for seborrhœa, is rarely successful in promoting a cure, although it is of undoubted value if begun early in life when excess of scurf is first noticed. In a recent post-graduate lecture[1] in Vienna, R. O. Stein pointed out that seborrhœa is common in African natives, and yet the bald man is seldom seen among them. Clearly there are other factors at work besides infection, and no one can fail to be struck by the close association of the state of the hair and the state of endocrine metabolism. In his first Lettsomian lecture last year Dr. H. W. Barber[2] said that "virility tends to loss of hair on the scalp with its increased luxuriance on the beard and body; feminism to a converse distribution." Sabouraud states that eunuchs are seldom if ever affected by the male type of baldness, and women, of course, show a similar immunity, which can be disturbed by endocrine disease. Dr. Barber mentioned a case in which a woman with a suprarenal tumour grew a beard and moustache, and went bald like a man. When the tumour was removed the hair on the face fell off, and the scalp regained its covering, but the signs of virility again returned with recurrence of the tumour. It is, perhaps, something of an anti-climax to recall that popular belief attributes baldness to the wearing of a tight hat—a view which is shared to some extent by dermatologists. W. A. Pusey[3] has lately remarked that "in the common occurrence of baldness we have a manifestation of a transitional stage in man's evolution..... Man now uses a hat instead of relying upon a shock of hair as his ancestors did..... This does not mean that we can save our hair by discarding our hats. We are a result of our ancestors, and to save our hair we should have to discard the hats of all our ancestors for scores of generations back." There is a certain amount to be said for this "vestigial" ætiology of baldness, but it has to reckon with a persistence of the axillary and pubic hair, which has survived in spite of all our clothing. Every theory yet devised has its weak spots, and at present it looks as though alopecia presenilis would long continue to embarrass the profession and enrich the advertising quack.

RUMINATION IN MAN.

Three hundred years ago Jerome Fabricius of Aquapendenta recorded the case of a young man who began to ruminate through worry because his father's forehead had suddenly sprouted horns—a state of affairs calculated to disturb even the least filial. Dr. Charles-Franceis Long, who quoted this story before the College of Physicians of Philadelphia, has collected[4] six cases exhibiting the phenomenon of rumination, and has investigated some of them radiographically, with a view to determining the mechanism of the act. Three out of the six subjects were Russian Jews, and all were of the fidgetty and neurasthenic type. Only one appears to have appreciated the commercial value of his condition, and he was an Egyptian who publicly performed prodigies of swallowing and regurgitation, finishing regularly with half a pint of kerosine, which was expelled in jets over a lighted candle, and produced a series of spurts of flame. Most ruminants, Dr. Long discovered, were hasty and large eaters, and were at great pains to conceal their ruminating faculty from their friends and relations. The food usually returned to the mouth without effort, 15 to 30 minutes after the meal, in the state in which it was swallowed, and could be re-masticated; the process stopped automatically as soon as the food began to taste sour. Most of the patients derived considerable pleasure from the second mastication, one of them insisting that it doubled the enjoyment of a good dessert. In most cases there was no selective power over the type of food returned, though the Egyptian actor claimed to have this faculty. The hereditary aspect has been stressed by other writers, but Dr. Long found evidence of this only in the family history of the actor. Rumination in the cow, as investigated by Toussaint 50 years ago, is, he says, associated with reduction in the intrathoracic pressure, and aspiration of the food out of the passive rumen. In the two cases which Dr. Long examined radiographically no evidence was found of an analogous mechanism in human ruminants, except that, as with herbivora, the act was preceded immediately by one of swallowing, which induced relaxation of the cardia. In the first case examined radiographically the stomach showed a functional hour-glass constriction, and when rumination occurred the food was squeezed out of the upper pole by a general contraction of the muscle wall. In the second case, which was that of the actor, the stomach was enormously distended, and some of the barium passed through into the small intestine. The stomach was apparently emptied both by contraction of the abdominal muscles and by generalised contraction of the whole stomach wall. The lower end of the œsophagus during the act showed a series of rhythmic contractions and relaxations; no peristalsis or reverse peristalsis was observed in the intestine. That this man was not a case of voluntary vomiting was shown by the history, which was that of a ruminant who had developed his peculiar faculty to the utmost, and by his capacity for controlling the amount of food returned.

GRATUITOUS SPLINTS AND SURGICAL APPLIANCES.

THREE months ago we brought the fact to the notice of many whom it interested actively that the Government contractors, Messrs. A. Fleming and Co. (39, Victoria-street, London, S.W.) had on their hands a stock of splints and kindred appliances taken over from the R.A.M.C. stores at the termination of the war. The contractors informed us then of their intention to give away free of charge to hospitals, infirmaries, and similar institutions large quantities of this stock which was all new and, though sometimes store-soiled, in thoroughly serviceable condition. The contractors are repeating this offer, as, although over 2000 splints of various types and patterns have been distributed and applications have been received from places as far away as China, the supply available is not exhausted. We learn from them, however, that inquiries are still being received for the appliances, and for particulars of the generous scheme of Mr. Alfred Fleming—for it is he who has been personally responsible for distributing the material which was purchased by him from the Government. The following apparatus is held at the disposal of suitable applicants:—

Leg and thigh splints, wood, Liston's pattern, in sets of three, with and without footpieces.
Extension apparatus, Guy's pattern, complete with clamp, shot can, pulley and cord.
Arm extension splints, with leather padded swivel ring.
Sinclair's modification of Thomas's knee splint.
Back, leg, and thigh splints, Nevill's pattern, white enamelled iron. No pads or straps available.
Footpieces, wire, for use with Thomas's leg splints.
Footpiece supports, iron, for use with Thomas's leg splints.
Leg splints, Thomas's, large with leather padded fixed ring.
Pattens's japanned iron, for use with Thomas's leg splints.

The scope of the donations, which were originally confined to hospitals (including homes for cripples) and infirmaries, is now enlarged and the offer is extended to establishments where training is given in first aid, and we are authorised to say that a large number of splints and other appliances can be disposed of in this generous way free of charge provided the recipients pay the carriage from the depot at Portsmouth to their own door. To institutions which have not taken advantage of this offer we bring it to their notice, for the need for surgical appliances must surely have increased with the increasing number of road accidents through motor traffic. To many institutions whose geography has exposed them to the expense of dealing with these accidents the chance for replenishing a heavy drain on their stocks will be welcome.

SPEECH AND INTELLIGENCE IN CHILDHOOD.

WHERE there is any question of retarded development it is important to find out just when the various bodily functions have been acquired; for these milestones of infancy and childhood often afford the only reliable evidence bearing on the onset of defects. Certain of them, such as the times of sitting, standing, walking, and talking are so constant as to furnish useful information. Others, such as the acquisition of sphincter control, are much more variable, and it is usually thought inadvisable to attach diagnostic importance to them. Of all the milestones which are of practical value, the beginning of speech is perhaps the most important, but it is also the least easy to recognise, because of the long time between early essays and finished perfection in this art. Taking the onset of speech to mean the age at which the child "utters a sound with full consciousness of its meaning and for the purpose of communication," Prof. Abt and co-workers[1] have made an extensive investigation into the records of 1000 cases examined at the Institute for Juvenile Research at Chicago, where the age of onset of talking, walking, and bladder control, the mental age and intelligence quotient (I.Q.), and other data have been recorded. The investigation was intended to apply to children whose faculties were within normal limits, and cases with gross mental defect, deafness, or anatomical abnormalities were discarded, as also were those concerning whom the replies were unduly vague. Analysis of these records showed a very close correspondence between the age of onset of speech and the I.Q. at the time the child was seen; but there was great variation in the ages at which the children were examined. The chart in which this correspondence is graphically displayed suggests that the higher the (subsequent) I.Q. the earlier the child learnt to talk. Very similar results were obtained by comparison of the general intelligence with the age of onset of walking. It has been stated that the ordinal position of the child in the family has an influence on the age of onset of speech—the younger ones reaping an advantage from their opportunities of imitation; but Abt and his colleagues failed to find any evidence of this influence. From the records of a small group of cases it appeared that prematurity was also without influence on speech. It was found, however, that the average age of learning to speak was considerably lower (17 months) in the group of children who had acquired sphincter control at 3 than the corresponding age (21 months) in the group which had not. The conclusions drawn from this interesting study are mainly consonant with the views most commonly accepted in this country, except that so close a correspondence between the onset of speech and of bladder control has not perhaps been recognised here. When applying the conclusions to clinical problems it should be borne in mind that the writers of this paper were investigating the *average* and not the *normal*. A point which remains unsettled, and on which opinion differs a good deal, is the extent of variation which constitutes pathological retardation sufficient to have a prognostic significance. All cases with physical defects were wisely excluded from the American series. The difficulties presented by deafness are well known, but one of the commonest causes of error in diagnosis and prognosis is the application of speech development as a test of intelligence in children who have suffered cerebral damage.

SLEEP AND INTRACRANIAL PRESSURE.

SOME investigations of the relationship between sleep and intracranial pressure have recently been reported by Stevenson, Christensen, and Wortis,[2] who have studied variations in the intracranial pressure in five patients who had a cranial defect resulting from operation. They employed an apparatus consisting of a closed air tambour system under a positive pressure of about 12 mm. of mercury. One tambour was strapped and bandaged over the brain hernia, and the other was attached to a light-weight pointer which registered on a smoked drum changes of intracranial pressure produced by the pulse, respiration, sleep, and the administration of certain drugs. A number of observations were made upon patients during the period of falling asleep and of awakening. The tracings constantly showed a rise of pressure associated with falling asleep and a fall of pressure corresponding to awakening. The effect of administering certain drugs was very interesting. Morphia was found to cause a rise in intracranial pressure and caffeine a fall. The authors are influenced by their observations to lay stress upon changes in intracranial pressure as playing an important part in the causation of sleep and of awakening. They attribute sleep to a periodical fatigue of "sympathetic centre in the brain which maintains vasomotor tone in the vessels." This is assumed to produce a vasodilatation of the blood-vessels of the brain as a result of which the brain volume becomes increased "with a consequent falling apart of the neurons." The pressure of the cerebrospinal fluid within the brain is also increased and this may alter the conductivity of the synapse. This mechanical view of the nature of sleep can hardly be reconciled with the conception of sleep as inhibition which Pavlov has proposed. Stevenson and his colleagues assume that the changes in intracranial pressure which accompany sleep and awakening are themselves causative factors of these changes of state. It may, however, be assumed with equal justification that the changes in intracranial pressure are secondary to the onset of sleep and its cessation. The latter view is supported by the fact that although pathological states of increased intracranial pressure are sometimes associated with drowsiness this is by no means always the case. Further, even if we accept the existence of the hypothetical sympathetic centre controlling the tone of the cerebral blood-vessels we have still to explain its periodical fatigue. It is doubtful, then, whether the purely mechanical view of the nature of sleep can be accepted. Nevertheless, the experiments reported are of considerable interest to those who are concerned with pathological variations in the intracranial pressure. The observation that caffeine lowers the intracranial pressure may have practical value in treatment and may explain the benefit derived from its use in such conditions as migraine. Diuretin has already been used by Marriott in the treatment of hydrocephalus in children.

RECTAL EXAMINATION IN LABOUR.

ALTHOUGH used as a routine in certain foreign clinics for upwards of a quarter of a century, rectal examination in labour has never been widely adopted in this country. The reason probably is that few British obstetricians have been convinced that the greater safety from puerperal sepsis compensates for its obvious disadvantages. The subject has lately been considered anew by La Vake,[1] and the advantages he claims for rectal examination, which he has used regularly since 1913, are briefly as follows: (1) There is no risk of introducing bacteria into the vagina. (2) Repeated examinations can be made in all types of surroundings without increase in danger. (3) The time of the attendant is saved because no elaborate preparations are required before examination. (4) In over 95 per cent. of cases that will end spontaneously, the rectal and abdominal examinations give all the data needed for diagnosis. (5) After rectal examination any operative interference can be undertaken with the assurance that pathogenic organisms have not been introduced into the vagina. (6) Absence of vaginal examination increases the confidence of the patient and the medical attendant. With regard to technique, La Vake points out that care should be taken to avoid soiling the external genitalia and that the thumb must be kept away from the vulva. He admits that investigation per rectum is more difficult for the student to master than investigation per vaginam, but he thinks this is more than offset by the much greater frequency with which it can be done. The best way to start the teaching of rectal examination is to begin in the gynæcological and out-patient department "where on all gynæcological, and on all pregnant patients in the early months, the recto-vaginal examination may be made and the student can check up his rectal findings by his findings with the vaginal finger. . . . Rectal examinations alone of patients in the last six weeks of pregnancy, especially in multiparæ, are most instructive, because in many of these cases the presenting part is easily felt and obliteration of the cervical canal and even dilatation has in many instances gone far enough to be distinctly manifest."

It would have been of great interest had La Vake given details of the incidence of sepsis in his clinic during the 16 years that rectal examination has been practised. He is content, however, with the general statement "each year's experience in all types of situations and conditions has added to my conviction that the rectal examination is potentially the safer examination, and the vaginal examination under the most meticulous aseptic technique should be used only when the rectal findings leave one in doubt. It is my belief that the universal teaching and use of the rectal examination. . . would reduce the incidence of postpartum sepsis." The figures he quotes from other clinics tend to support, but certainly do not prove, this contention. Guggisberg, at Berne, employed vaginal examination from 1901 to 1911 in 4642 cases; in 17·5 per cent. the temperature reached 37·5° C. (99·5° F.), genital infection occurred in 11·2 per cent., and death from sepsis in 0·12 per cent. From 1912 to 1921 3010 cases underwent rectal examination only; the temperature reached 37·5° C. in 11 per cent., genital infection occurred in 5·5 per cent., and there were no deaths from sepsis. The balance here was decidedly in favour of rectal examination. In a similar study by Reis, the number of cases was smaller, but they were all seen in one year (1924), and the conditions in the two sets of cases were more likely to be comparable; 609 cases were examined by the vagina, 271 by the rectum, and 106 not at all. The pelvis was infected in 6·3 per cent. of those rectally examined, in 5·9 per cent. of those examined vaginally, and in 4·7 per cent. of those who had no examination. Reis also tabulated his cases according as they were febrile or afebrile; any patient showing more than half a degree rise of temperature at any time during the first seven days after delivery was considered for the purpose of this investigation as being febrile. Comparing the cases delivered spontaneously, it was found that of those who had rectal examination 54 per cent. were afebrile; of those examined vaginally, 57 per cent. were afebrile, while of those who were not examined either vaginally or rectally, 64 per cent. were afebrile. Reis therefore concluded that the percentage of absolutely afebrile cases is definitely increased when neither rectal nor vaginal examination is made, and conversely that the percentage of pelvic infection is definitely decreased, but that there appears to be "practically no difference between the group examined vaginally and the group examined rectally."

On the whole no strong case seems to have been yet made out on behalf of rectal examination. Possibly the question can never be decided until we have a final pronouncement on the pathogenicity of the flora of the normal vaginal canal. If the organisms normally present are either actually or potentially pathogenic, then rectal examination might be as effective as vaginal examination in introducing them into the interior of the uterus.

CHILD WELFARE IN AUSTRIA.

THE Commonwealth Fund is now actively promoting schemes for child welfare in Europe as well as in America, and the directors of that branch of the Fund which serves Austria have issued a report[1] of their efforts over a period of six years. They have followed the excellent American practice of subscribing generously to any venture which they have helped to set on foot, while not subsidising it entirely. This guards against the collapse of a project when funds are withdrawn, and has the added advantage of stimulating local effort. The difficulties of coördinating health organisation in post-war Austria are well described; the independence of the nine provinces, with feudal traditions suddenly overthrown but still in the minds of the people, and the shattered economic situation, make this no easy field for health work. The character of the Austrians, however, lends them stability in their disorganised environment. They are receptive, and readily inclined to take an intelligent interest in fresh views, while the autocratic Government to which they were formerly accustomed has made them amenable to direction and guidance; for example, the patients attend unquestioningly at the clinics on the date fixed by the doctor. But the intensely local patriotism of each province makes any central organisation impracticable at the present time. Medical assistance for the sick child after the war was obtainable in Austria by means of several different agencies. One way was through the health insurance societies, or Krankenkassen, which provided treatment for the families of their members; another was through private child health stations instituted and run by doctors; a third was through the city health stations, or Jugendämter, with which there came to be associated after the war a group of trained workers called the Fürsorgerinnen. The functions of these home workers cannot be exactly matched elsewhere; they combine advice on child welfare to the mothers with a knowledge of standardised procedure in social problems; that is to say, they arrange for State care of illegitimate and orphan children where necessary, and for reception into institutions of tuberculous or mentally defective cases. Their influence among the peasantry is large, and has been of great assistance in solidifying the new health schemes which the Commonwealth Fund has helped to set on foot. For every province the reorganisation of child health work had to be approached in a different manner. The report gives a detailed account of the various methods employed and the results obtained. The aim has been throughout to exert a unifying influence, and the Fund has done much to coördinate the work of the health centres in each province, to promote a friendly spirit between the staffs of the different clinics, and to provide facilities for foreign travel and instructional courses for the workers. This has had an encouraging effect on the general efficiency of the service, and has greatly stimulated the interest of those engaged in it. Gifts of equipment have been made by the Fund, and assistance given in improving old quarters or obtaining new ones. This coöperation has helped considerably to relieve the post-war depression in the Austrian medical service.

INFECTION AS A CAUSE OF DIABETES MELLITUS.

THE ætiology of diabetes mellitus remains a problem of great complexity. The classical experiments of Minkowski and von Mering[1] on the effects of pancreatectomy and the isolation of insulin indicate that the essential defect is an inadequate supply of the pancreatic hormone. Many factors, however, are known to be capable of thus adversely affecting the secretion of insulin, and diabetes must be regarded, not as a morbid entity, but as the end-result of a variety of pathological processes. In a minority of cases the chain of events is relatively simple. In the diabetes which sometimes complicates hyperthyroidism, for example, it is probable that over-activity of the thyroid leads to over-stimulation, followed by exhaustion, of the β cells of the islets of Langerhans. In the great majority of cases of diabetes, however, the damaging agent is not obvious. At a recent meeting of the Pathological Society of Manchester Dr. T. H. Oliver and Dr. G. J. Langley discussed the possibility that diabetes is sometimes infectious in origin. There is much circumstantial evidence in favour of this view. Various bacterial and allied poisons, such as diphtheria toxin (Tisdall, Drake, and Brown[2]), typhoid vaccine, and histamine are known to lower carbohydrate tolerance in animals, and in human diabetes coincident infection very frequently causes a temporary or even a permanent decrease in the response to insulin, and often precipitates coma. Dental sepsis is almost universal in diabetic patients, but, while it is attractive to attribute diabetes to continued absorption of bacterial toxins from the teeth sockets, it must not be forgotten that the dental infection may be the result of that lowered resistance to bacterial invasion which is common to all diabetics. In young subjects diabetes occasionally follows an acute infectious disease such as mumps, and in many cases of acute diabetes the onset of the symptoms can be traced to an indefinite febrile illness. These considerations have led many observers (cf. Frissell and Hajek[3]) to suggest an infectious origin in such cases. Bergey's claim[4] to have isolated from diabetic urine a filter-passing virus capable of producing glycosuria in rabbits does not appear to have been substantiated, but a virus infection, analogous to mumps, may well be concerned. If this is so, since diabetes is not contagious, the virus must be widespread and, like the virus of febrile herpes, must remain latent until activated by some other infection.

Infection undoubtedly plays some part in the production of diabetes; how large a part this is remains uncertain.

A RELIABLE TEST FOR PREGNANCY.

LAST week, in recording inconclusive though encouraging results of attempts to get clinical improvement by injections of œstrin, we had occasion to regret that the sexual cycle in man has no exact parallel in the animal world. In this issue of THE LANCET Dr. H. Allan and Dr. F. Dickens show that man's peculiarities in this respect can sometimes be exploited to good advantage. If the pregnancy test devised by Zondek and Aschheim had been tried out on domestic animals, such as cows, where early knowledge of impregnation would be of great value to dairy farmers, it might easily have been dismissed as worthless; in the few pregnant animals tested—cows, cats, and rabbits—the results obtained were negative. Fortunately the urine of pregnant women appears to contain a hormone which, when injected into immature mice, produces changes in the ovary that can mostly be recognised macroscopically. This hormone is not œstrin, which is also present in the urine and, as our Berlin correspondent reports, may be obtained from this source in an extraordinary state of purity. Œstrin, however, produces no such change in the ovaries, though it has an effect on the development of the immature uterus and vagina. Zondek and Aschheim believe the active hormone to be anterior pituitary.

From the clinical point of view the important fact is that critical observers such as those working at the Courtauld Institute of Biochemistry of the Middlesex Hospital, under Prof. E. C. Dodds, have found that among 126 women known to be pregnant 122 gave a positive test, while only 1 out of 82 non-pregnant women did so. Moreover, the patients selected were at an early stage of pregnancy when clinical diagnosis is still difficult. The test seems to be sufficiently reliable for all clinical purposes, and has the further advantage that in delicate circumstances it can be done without the knowledge of the patient or her friends. The technique needs practice, but is likely to be acquired by clinical pathologists now that the value of the test has been confirmed. The family doctor will be grateful for the simplicity of his share, which consists only in collecting morning urine from the patient and possibly adding a drop of tricresol as a preservative.

A SERVICEABLE LIBEL.

A WEEK or two ago our Paris correspondent told how a physician of good repute had exposed a "specific" against tuberculosis composed of cigarette paper soaked and crumbled, and had called the inventor of this priceless remedy a thief and a quack. For this language Dr. Nast was sued for libel, although it was anticipated that, even if he was convicted, the court would let him off lightly. This has proved to be the case, for the sentence passed on Dr. Nast carries the minimal penalty allowed by law—namely, 1 franc of damages to the inventor of the "specific" and a fine of 25 francs, which need only be paid if the malefactor is again convicted within the next five years. It is customary in France for one who is convicted of libel to be ordered to insert an apology in specified newspapers at his own expense, which may be considerable. Dr. Nast has not been required to make any such insertions. The action of the court is regarded as of real significance in medical circles, for, generally speaking, French judges are not specially indulgent to medical men, and have sometimes been regarded as giving them more than their deserts. Dr. Nast, it is clear, is regarded as having done public service in exposing a remedy which had received extravagant prominence in the press to such effect that sanatorium practice was endangered and patients seriously upset by the withholding of a remedy from which they had been led to expect so much. There is still a possibility that the inventor himself may get into trouble for having practised medicine without any qualification.

THE CHAIR OF MEDICINE IN THE UNIVERSITY OF ABERDEEN.

THE Regius Chair of Medicine in the University o Aberdeen is the oldest foundation for the teaching of medicine in Great Britain, and an interesting departure in filling the appointment has occurred, following the resignation of Prof. Ashley Mackintosh. Hitherto the Professorship has been held as a part-time appointment with a salary of £850 a year. Henceforth a salary of £1200 will be attached to the Chair, in view of the Professor being expected to devote more time to teaching and to the initiation and conduct of research. Further, the holder of the Chair becomes honorary physician to the Royal Infirmary of Aberdeen, and, having charge of beds, will be in a position to associate the activities of research with clinical practice. The appointment to the Professorship is made by the Crown on the recommendation of the Secretary of State for Scotland, and there should be, and quickly, strong candidates in the field, for the opportunities of doing valuable work are obvious, especially as additional assistance and full facilities for the conduct of research are to be provided.

MEDICAL STAFF OF THE MINISTRY OF HEALTH.—Following the retirement of Dr. F. J. H. Coutts, from the post of senior medical officer for tuberculosis, venereal disease and general institutional therapy, this appointment will be held by Dr. A. S. MacNalty, while Dr. J. Alison Glover has become deputy senior medical officer. Dr. A. W. J. MacFadden, the senior medical officer with supervision of food supplies, is succeeded by Dr. Thomas Carnwath, this section being enlarged to include therapeutic substances, medical aspects of water supply and the medical administration of the Local Government Act in London. Dr. Miles B. Arnold takes the place of Dr. J. R. Hutchinson as deputy senior medical officer to Dr. H. A. Macewen in the section of sanitary administration, and Dr. Hutchinson has been appointed deputy senior medical officer to Sir George Buchanan in the section of general health and epidemiology.

Modern Technique in Treatment.

A Series of Special Articles, contributed by invitation, on the Treatment of Medical and Surgical Conditions.

CCXCVII.

TREATMENT OF THE TYPHOID FEVERS.

PART I.*

Typhoid fever is a disease peculiar to man. Paratyphoid fever, on the other hand, occurs both in man and in domestic animals—dogs, cats, pigs, rabbits, and parrots (Vincent and Muratet)—and may be transmitted from these animals to man. Three varieties of paratyphoid infection are described—para. A, para. B, para. C; of these para. B is the most frequent in the British Isles.

Differential Diagnosis between the Typhoid Fevers.

Though paratyphoid fever is usually less severe and of shorter duration than typhoid is wont to be, the same complications may occur in both infections, and for this reason precisely the same care and precautions are to be observed in treating the one as the other. In paratyphoid the incubation period may be shorter than the 12 days of typhoid; the onset may be abrupt, even with a rigor; the pyrexia is seldom of the continuous type, often showing a daily variation of 2° or 3°; termination by lysis may take place in the third week. In paratyphoid, symptoms referable to the respiratory system may dominate the clinical picture with or without physical signs of broncho-pneumonia. In paratyphoid, the septicæmic stage, during which diagnosis may be made by blood culture, usually lasts but three or four days, whereas in typhoid a positive blood culture is often obtainable for the first week or ten days; only in very grave cases does a demonstrable septicæmia persist. In paratyphoid, the colon may be the chief seat of ulceration; in typhoid, ulceration of the intestine is often confined to the Peyer's patches of the lower six feet of the ileum. The specific bacillus in paratyphoid B may be demonstrated in the stools more constantly than is the case of *B. typhosus* in typhoid fever—a fact which renders examination of the stool of great value in the diagnosis of paratyphoid. The leucopenia characteristic of typhoid fever after the first few days is inconstant in the paratyphoid infections, and may indeed be replaced by a moderate leucocytosis.

General Management of the Case.

As soon as typhoid fever is suspected the patient is confined strictly to bed; the earlier absolute rest is enforced the greater is the chance of recovery. Intelligent nurses for day and night duty are essential. The ideal room in which to nurse the patient is quiet, large, light and airy, getting the sun yet capable of being darkened, and with adequate lavatory accommodation close at hand. The bed is a single one, mounted on wheel castors, with a firm mattress, and so placed that the nurses can walk round it; not more than two pillows are allowed. A water bed is not necessary but an air ring is to be provided. When feasible, the patient's comfort is enhanced by the provision of two similar beds, one for day and the other for night; when the beds are wheeled side by side, the patient may be lifted from the one to the other with but little disturbance.

Special china and cutlery is set apart for the patient's sole use; and arrangements are made for disinfection of the nurse's hands, of the patient's excreta, and of all objects with which he comes in contact. The specific organism may be discharged in the stool, in vomit, in urine, in sputum, and in any purulent discharge which may be present; all such materies morbi demand disinfection. The fæces, after inspection, are thoroughly mixed with an equal volume of 1 in 20 carbolic solution, and allowed to stand for one hour before being disposed of; to the urine half its volume of 1 in 20 carbolic is added, and the vessel washed out with this solution after use. Sponges and cloths used for washing the patient are disinfected after use, and all bed linen and clothing soaked in carbolic before being sent to the laundry; the crockery is sterilised by boiling after use. Flies are denied access to the sick quarters.

---

* Part II. will appear next week.

However ill the patient may be, the whole body is washed at least once a day with soap and water, the pressure points receiving frequent and special attention in order to prevent bed sores, to which end also, and to avoid hypostatic congestion, the patient's position is changed every four hours. The mouth also requires especial care; a thorough cleansing after each feed should be undertaken either by the patient himself or by his nurse. An efficient and pleasant mouth-wash is furnished by adding a teaspoonful of the following mixture to half a tumbler of water:—

℞	Liq. potassæ	ʒ 1
	Ac. carbol.	ʒ 4
	Tr. cocci	q.s.
	Aquam ad	℥ 6

Any tendency to dryness of the lips may be checked by the application of a simple ointment.

If the temperature rises above 103° F. the patient is cradled; when it exceeds 104° sponging with hot water (110°) is just as efficacious as is tepid sponging for the reduction of pyrexia, and is less likely to cause discomfort.

As a rule the typhoid patient is to be awakened at night when feeds are due; attempts are to be made to check mouth-breathing when it occurs, as thereby dryness of the mouth is aggravated.

The patient is kept in bed for at least two weeks after defervescence is complete; a week is occupied in the process of getting up, careful watch being kept for increase in pulse frequency which, should it occur, is an indication for more rest. In a case of any severity the patient will not be fit to return to work for three months.

Before the patient is discharged the stools and urine should be examined for the specific organism three times at five-day intervals. But even with three negative reports a carrier may be overlooked. The treatment of carriers is unsatisfactory; even when there is evidence of cholecystitis or of cholelithiasis removal of the gall-bladder may not be successful in curing the carrier state since the bile ducts may be infected. In order to prevent spread of the disease a carrier should not be permitted to work in the preparation or handling of food for human use, and prophylactic inoculation of contacts is advisable.

It is a wise precaution to give at once prophylactic vaccine to nurses and other members of the household who have not already suffered from the disease or been inoculated within two years. Three subcutaneous injections of mixed TAB vaccine are given at ten-day intervals; for an adult the first dose is 500 million typhoid and 250 million each of para. B and para. A. The dose is doubled at each succeeding injection.

Feeding.

The patient is not to be propped up in bed for feeding, or any other purpose, until the temperature has been down for at least seven days; fluids are given in a feeding cup or sucked through a tube, other articles administered with a spoon.

Throughout the whole course of typhoid fever the patient is encouraged to take food. Though milk is the mainstay there is no reason why certain solid articles should not be allowed, so long as the patient is able to masticate them thoroughly and has the desire for them; mastication increases the flow of saliva and is an important factor in keeping the mouth clean and in preventing septic parotitis. A liberal diet in the early stages helps to maintain the patient's strength, and so prepare him the better to withstand certain complications which may arise later, the incidence of which is not diminished by relative starvation. An accurate record is to be kept of the quantity and composition of all feeds given; in the choice of food, the patient's own likes and dislikes are carefully considered, but more must not be given than he is able to digest. In addition to the regular feeds at stated times, he is urged to take sufficient water or lemonade in between times to bring the total liquid consumption up to five or six pints in the 24 hours. This promotes diuresis and aids in the elimination of toxins. Should vomiting occur, all food must be withheld for a few hours; diarrhœa often indicates a diet too rich in fat; abdominal distension calls for a reduction in carbohydrate.

W. Coleman considers the typhoid patient's food requirement is from 60–80 calories per kg. of body-weight per diem—i.e., nearly 5000 calories for a man weighing 11 st.; it is important that the daily carbohydrate ration should not fall below 50 g. lest acidosis develop.

During the first week of the disease, if headache is troublesome, the appetite is apt to be poor though thirst is not seldom a complaint. At this stage the daily diet, exclusive of water, consists of 3 pints of milk, 2 eggs, 1½ oz. of cream, and 3 oz. of lactose (calorie value approximately 1550). A feed of, say, 6½ oz. is given two-hourly by day and four-hourly by night, the eggs being beaten up with four of the feeds or made into custard. Milk without egg may be flavoured with tea, coffee, chocolate, or cocoa, and given either warm or iced in the feeding cup.

During the first few days the diet is tentatively increased by the addition of lactose and of cream—say, 1½ oz. of each a day up to a total of 6 or 8 oz., thus raising the calorie value to about 2500. Barley-sugar may be appreciated, especially by children. At the end of the first week, or before if the patient will take it, rusks, breakfast biscuits, or thin bread (without crust) and butter, honey or jelly, junket or blancmange, or 2 oz. of pounded steamed or boiled white fish and a little apple or prune purée with cream may be added gradually to the daily ration. Eggs may be lightly boiled. Feeds are now given three-hourly by day, and the patient is urged to drink water, or lemonade with added lactose, in the intervals. No further addition to the diet is permitted until convalescence is well advanced, though the frequency may be reduced, and the quantity of each feed correspondingly increased when defervescence is established. Certain individuals assert their inability to take plain milk. If this statement proves to be true, the addition of citrate, grs. 2 to the ounce of milk, or the substitution of malted milk or junket and whey may have the desired effect. Failing this the diet is to consist of plasmon and gruel, made from fine oatmeal or Robertson's barley passed through a sieve, thick vegetable soups, carefully strained, mashed baked potato, tapioca or bread pudding with the above-mentioned quantities of cream and lactose.

Following the pyrexial period, if all goes well, the temperature remains subnormal for a week or ten days; should it not do so, and in the absence of other obvious cause, a relapse or recrudescence is likely. The probability of a relapse is greater if the spleen remains palpable, and if Ehrlich's diazo reaction, which usually disappears with the commencement of lysis, again becomes positive in the urine (Rolleston).

Ehrlich's Diazo Reaction.—Requirements. Fresh solutions:
1. Saturated solution of sulphanilic acid in 1 in 20 HCl.
2. 0·5 per cent. aqueous solution of sodium nitrite.
3. Liquor ammon. fort.

Technique.—Fill a test-tube one-third full of urine and add an equal volume of sulphanilic acid solution. Mix by inverting, and add one drop of nitrite solution. Shake to frothing, and add ammonia slowly. A positive reaction is indicated by a pink coloration of the froth, the urine becoming deep crimson.

A relapse is treated in the same fashion as the primary attack.

The Bowels.

The use of the bed pan is insisted upon from the very start of the illness until the temperature has been subnormal for at least seven days.

No aperient is given by the mouth from the end of the first week until at least ten days after defervescence is complete, lest ulceration still be present. Constipation and diarrhoea may usually be controlled by alterations in diet. It is most important that the stools be soft; if the fæces are hard or defæcation difficult, the amount of fat and lactose in the diet is increased, provided nausea and meteorism is not induced thereby. Should the addition of fat not be tolerated, the quantity of milk is reduced and an equal amount of beef-tea or clear chicken soup substituted. A dessertspoonful of liquid paraffin two or three times a day, or a glycerine suppository may help matters, but if the fæces are still hard or difficult to expel, a plain soap-and-water enema is given on alternate days. When diarrhoea —more than three of four actions in the 24 hours— does not respond to a reduction of fat, or to the substitution of malted milk for plain milk, it is necessary to give small doses of Dover's powder which may be combined with kaolin. Tenesmus, in association with diarrhoea, may be checked by a rectal wash-out with a pint of warm normal saline solution followed by a belladonna suppository, or starch and opium (tr. opii ♏xxx.–xlv. in starch emulsion ℥iv.) given cold through a catheter, the tip of which is inserted just beyond the internal sphincter.

Abdominal *distension* usually indicates a diet too rich in carbohydrate, but in profoundly toxic cases it may be paralytic in origin. Distension is a serious condition, and one which the physician must constantly be on the alert to detect when carrying out the daily inspection of the abdomen. At the first sign of distension the carbohydrate intake is reduced and the total fluid cut down to 3½ pints; milk infected with *B. bulgaricus* or *B. acidophilus* is useful in certain cases. When the colon is mainly affected, tr. asafetidæ ʒii. in mucilage of starch ℥iv. may be injected into the rectum. If the condition persists and is not associated with hæmorrhage, heat is applied to the abdomen, and an emulsion of ♏xx. of turpentine or a capsule containing ♏v. of oil of cinnamon given by mouth two- or four-hourly, and a half pint ox gall enema. Collosol kaolin ʒiii. in water ℥iv., given by the mouth three or four times a day is often useful. Should these measures fail, a hypodermic of eserine sulphate, gr. 1/200 combined with strychnine, gr. 1/60 must be given, and repeated in four hours if necessary; alternately, an intramuscular injection of pituitrin ½ c.cm., may be used.

Urine.

The quantity of *urine* passed is to be recorded. Retention of urine is not infrequent quite early in the disease; when fomentations fail to relieve the condition, which is usually of short duration, catheterisation at stated intervals is necessary. If "incontinence" occurs take care lest the condition be retention overflow; passage of a catheter may be necessary for diagnosis when meteorism is present.

Special watch is to be kept after the second week for the occurrence of bacilluria. In this condition the urine is generally pale in colour and uniformly turbid. The turbidity does not clear on standing, nor is it removed by ordinary filtration; the specimen gives a peculiar satiny shimmer when gently shaken.

THE ZONDEK AND ASCHHEIM TEST FOR PREGNANCY.

BY H. ALLAN, B.Sc. LOND., A.I.C.,
ASSISTANT IN THE COURTAULD INSTITUTE;
AND
F. DICKENS, M.A. CAMB., PH.D. LOND.,
WHOLE-TIME WORKER FOR THE MEDICAL RESEARCH COUNCIL.

(From the Courtauld Institute of Biochemistry, Middlesex Hospital, London.)

RECENT work on the sex hormones has provided an entirely new basis for a test for pregnancy. In 1927 Zondek and Aschheim [1] described experiments showing that implantations of male or female pituitary tissue into immature female mice produced precocious sexual maturity. The most noticeable external changes were: (*a*) the canalisation of the vagina and (*b*) the appearance of œstrus, as judged by the vaginal smear. Post-mortem examination of these animals revealed that the uteri were hyperæmic and greatly enlarged; the ovaries were much increased in size, and there were present on them some minute dark spots—termed by Zondek and Aschheim "Blutpunkte." In the following account these are referred to as "corpora hæmorrhagica." Examination of sections of the ovaries from the treated mice showed that a very large proportion of the follicles present in the ovary had become mature; that the corpora hæmorrhagica were, in fact, unruptured follicles into which blood had been extravasated, and, further, that a number of corpora lutea were frequently to be seen, some of which contained a degenerating ovum. The corpora lutea of the latter type, which were evidently formed without previous rupture of the follicles, are the so-called "corpora lutea atretica." Later [2,3] these authors observed that during pregnancy a hormone producing effects closely resembling those brought about by implantation of anterior pituitary tissue appears in the urine; this observation forms the basis of the test for pregnancy now under consideration.

It may be remarked here that Smith and Engle [4] have arrived at slightly different conclusions as to the effects produced by implantation of anterior pituitary substance into immature animals. They find that ripening of the Graafian follicles and ovulation are the principal effects, and that atretic follicles are, in fact, *less* frequently seen than in the normal adult animal; also they do not find corpora hæmorrhagica. Whatever the explanation of this difference may prove to be, it is to be regarded as an important theoretical point which may be considered apart from any estimate of the practical value of the Zondek and Aschheim test. There is no doubt that the effects of injection of urine from pregnant women into immature mice are as described by Zondek and Aschheim, and that these changes can readily be obtained by the injection of small quantities of the untreated urine. The presence in the urine of a substance capable of bringing about the above results is considered by Zondek and Aschheim (*loc. cit.*) as diagnostic of pregnancy, and the results obtained on a large number of cases are brought forward by Aschheim [3] in support of this conclusion.

In view of the importance of a satisfactory means of diagnosing pregnancy, we decided to investigate the reliability of the test in this laboratory. The methods employed and the results obtained are described below.

Experimental.

Urine.—Specimens from the early morning urine were obtained where possible. When the urine had to be kept for a few days before testing it was stored in a refrigerator at -5° C. If some time was likely to elapse between the passing of the urine and its arrival at the hospital, a trace of tricresol was placed in the collecting bottle to prevent bacterial action. Very slight decomposition of the urine leads to a high mortality in the test animals.

Animals.—For each specimen five or more mice were used. Owing to the difficulty of raising the large numbers required, the mice were purchased from the breeders.* The age of the mice at the beginning of the test was 21 to 24 days, and it is essential that this latter age should not be exceeded. The average weight was 7·5 g., thus indicating that the animals were satisfactory in this respect.

Injections.—Each mouse received six injections of urine distributed as evenly as could conveniently be arranged over a period of 45 hours. The actual times of injection were:—

1st day ……..	12 noon ……..	6 P.M.
2nd day ……..	9 A.M. ……..	3 P.M.–9 P.M.
3rd day ……..	9 A.M.	

Originally the doses recommended by Zondek and Aschheim were used—namely, 6 doses of 0·4 c.cm. to one mouse, 6 of 0·3 c.cm. to another, and so on down to 6 doses of 0·2 c.cm. As we found that the mice receiving the largest doses sometimes showed less response than those receiving the small ones, we modified the procedure so that each animal receives 6 doses of 0·3 c.cm. It is then unnecessary to mark the individual animals. The only advantage in the varying dose seems to lie in the fact that with toxic specimens of urine the animals receiving the smaller doses sometimes survive, but it is usually preferable to obtain a fresh specimen and repeat the test. Not more than 1 drop of tricresol should be added to each 30 c.cm. of urine. The injections are made subcutaneously. Frank[5] states that in his hands the mice died during the test, before readings could be taken, but this has not been our experience. The mortality tends to be high when the investigator lacks experience, but rapidly diminishes with practice, when with the dose mentioned above only a few specimens of urine cause a serious death-rate.

The mice are killed on the morning of the fifth day and their ovaries and uteri are examined.

Interpretation of Examinations of Ovaries and Uteri.—The ovaries of the untreated mouse are small and contain unripened follicles; the uteri are thread-like, and the vagina is a solid cord of cells. Following the injection of urine a positive test is indicated by the presence of corpora hæmorrhagica or of corpora lutea in the ovaries. The former appear as red dots of varying size but frequently they are about the size of a pin's head. When present on the surface of the ovary they are easily seen and the appearance is quite characteristic. Occasionally they are very small, or are found in the body of the ovary, when their presence may be confirmed by squeezing the ovary, moistened with a drop of glycerol, under a coverslip and examining microscopically. In addition to the hæmorrhagic follicles, corpora lutea are frequently observed. They are most easily recognised by means of a lens. In a few cases it is found necessary to prepare serial sections of the ovaries, solely as confirmation of the macroscopic findings.

The presence in the ovary of either corpora hæmorrhagica or corpora lutea, or of both, constitutes a positive reaction. The test is reported as positive even if these changes occur in only one of the animals used. In our experience, corpora lutea are usually found to be accompanied by corpora hæmorrhagica, and in only four of a total of 126 positive tests were corpora lutea present without corpora hæmorrhagica. All four were normal pregnancies. Certain changes in the uterus, vagina, and vaginal smear are also usually observed. These are enlargement, thickening, and distension of the uterus, opening of the vagina, and sometimes the appearance of the cornified epithelial cells characteristic of œstrus, in the vaginal smear. These changes in the uterus and vagina, however, are due to the œstrus-producing hormone (œstrin), and are not necessarily indicative of pregnancy. The œstrin is derived either from the urine injected or else its presence is due to the liberation of increased amounts from the ovary of the mouse. Many workers have shown that during pregnancy the urine contains a much increased amount of œstrin (Zondek and Aschheim,[6, 2] Veler and Doisy,[7] Allan, Dickens, Dodds, and Howitt[8]). Œstrin, however, has no observable effect on the ovaries, and its presence is indicated solely by its effect on the uterus and vagina. The changes produced in the ovaries upon which the diagnosis is based must, therefore, be due to some other cause, and as has been stated, they are attributed by Zondek and Aschheim to the hormone of the anterior lobe of the pituitary.

Results.

237 specimens of human urine have been examined by the method described. Since there is no difficulty in the clinical diagnosis of advanced pregnancy we have, as far as possible, obtained urine from early pregnancies. In this we have been fortunate in having the coöperation of Mr. L. Carnac Rivett, who has secured most of these cases from Queen Mary's Hospital, Stratford, where the demand for accommodation leads to very early application to the hospital. Table I. shows the collected results.

TABLE I.

Specimens.	Cases.	Test pos.	Test neg.	Per cent. error.
Females definitely known—				
(*a*) to be pregnant	126	122	4	3·2
(*b*) not to be pregnant	82	1	81	1·2
Males	6	0	6	—

The results given in Table I. were mainly from cases of simple pregnancy. In addition the series given in Table II. reproduces the results obtained in a number of other conditions.

Discussion and Results.

From Table I. it is clear that a positive test may be relied upon in almost all cases. Only one specimen from a total of 208 pregnant and non-pregnant women gave an incorrect positive result. This case, a woman aged 46 years at the menopause, clinically presented no unusual features. The test was repeated on two separate specimens of urine. The first specimen gave a very feebly positive result in one of five mice, which showed on microscopic examination the presence of corpora lutea in both ovaries. The test was repeated when the reaction was negative. A new specimen was then procured, when the result was again positive, a small corpus hæmorrhagicum being present, in addition to a corpus luteum in the ovary of one of the eight mice used for the test; the remaining seven mice were negative. A positive result was not obtained in any of the other five cases at the menopause examined, and negative findings are reported also by Zondek and Aschheim in numerous cases. A possible explanation is furnished by the work of Fluhmann,[9] who has shown that after castration, natural or artificial, increased amounts of anterior pituitary hormone are found in the patient's blood. For some reason this particular woman excreted an amount of the hormone into the urine sufficient to give a weakly positive reaction to the Zondek and Aschheim test.

---

* The Mousery, Rayleigh, Essex.

Unlike the tests depending on the presence of the œstrus-producing hormone in the urine, the Zondek and Aschheim reaction is positive early in pregnancy. For example, in one case in which the onset of the menstrual period was only nine days overdue an intensely positive reaction was obtained; and in general it can be stated the test is certainly no weaker in the early cases than in the later ones.

The possible error is somewhat greater when a negative result is obtained. Of 126 pregnant women examined four showed a negative test. One woman miscarried three weeks after the performance of the test. The remainder proceeded to full term normally. The specimens of urine were not toxic, and the test proceeded normally in all four cases.

With regard to Table II., the rapid disappearance of the hormone from the urine following delivery or abortion is well shown. The persistence of the corpus luteum during lactation suggested that the urine might possibly contain sufficient luteinising hormone to give a positive test; this expectation was not fulfilled. At the onset of menstruation also the test was negative, and the hormone was not present in the urine of young girls, although the growth-promoting function of the anterior lobe is presumably very active at this time. Urine from one case of pituitary tumour in a girl of 17 has been tested. The patient showed typical optic phenomena, and the diagnosis was confirmed by X ray examination. The latter showed the growth to be confined to the posterior region of the pituitary fossa as indicated by erosion of the posterior clinoid processes. The result of the test was negative. The cases at menopause have already been described, and this is the only condition in Table II. where any confusion exists.

The animal experiments summarised in Table III. show that the test is not directly applicable to the rabbit, cat, or cow. In these species the urine was often so toxic that all the mice died, even when the urine was neutralised with acid before use, and occasionally after only one injection. Those tests where the survival was sufficiently high to permit any conclusion were uniformly negative. The results with the cow are disappointing in view of the practical importance of the diagnosis of pregnancy in this animal. We are greatly indebted to Dr. R. F. Montgomerie, veterinary adviser to the University College of North Wales, Bangor, for the trouble which he has taken in supplying us with these specimens.

TABLE III.—*Experiments with the Urine of Animals.*

Animal.		Animals.	Specimens.	Result of tests.
Rabbit pregnant		1	1	Neg.
		2	2	Both toxic.
" ovariectomised ..		2	2	Both neg.
Cats pregnant		1	1	Neg.
		2	2	Both toxic.
Cows (believed pregnant) ..		7	8	All toxic.
		2*	2	Both neg.
Cows' urine diluted before test.	× 5	2	2	"
	× 10	2	2	"

* One served 7 weeks previously: now definitely pregnant.

Conclusions.

Taken together, the results show that in the human subject the test may be relied upon with some confidence, the percentage of error being low for such a reaction.[†] Exceptions described are: (*a*) one case at the menopause giving a positive reaction; (*b*) four normal pregnancies giving a negative test without apparent cause. With this one exception all tests in which a positive result was obtained were correct. Clinical tests are now being discontinued, since the animals are required in connexion with work now in progress on the chemistry of the substances involved.

We wish to express thanks to those who have kindly placed material at our disposal, particularly to Mr. L. Carnac Rivett, Mr. F. W. Roques, and Mr. A. L. Walker, and also to Prof. E. C. Dodds, for the interest which he has shown in this investigation.

MEDICINE AND THE LAW.

Dr. Knowles's Successful Appeal.

IT is understood that the Judicial Committee of the Privy Council will not announce till February next the reasons for the decision announced on Nov. 19th, to advise His Majesty to allow the appeal of Dr. Benjamin Knowles from the judgment by which he was found guilty at Kumasi of the murder of his wife.

Dr. Starkie's Sentence Reduced.

Dr. Richard William Starkie, sentenced to 12 months' imprisonment in the second division at Maidenhead, on Dec. 2nd, for offences against the Dangerous Drugs Act, appealed to the county quarter sessions at Reading on Dec. 20th, on the ground that the sentence was excessive. Counsel prosecuting for the Crown recalled the facts. The appellant, an unregistered practitioner, had admitted his signature on 16 prescriptions for heroin presented during three months on behalf of a patient named Mrs. Melville. He had told a police inspector that on different *occasions he had given blank sheets of paper containing* his signature to a man named Melville or Vilmer. The appellant's counsel obtained the answer that there was no suggestion against Dr. Starkie of carrying on a traffic in drugs. He said that two registered practitioners had been persuaded by Vilmer to act as Dr. Starkie had done, and they had been convicted for not keeping proper records. Counsel also objected sharply to the statement of the prosecution in the court below that he had instructions from the Home Office to say that the case was regarded as a serious one. *He protested that this was improper, and that* the officials of a Government department had no right to form and publish their conclusion about a case without having heard a single word about it in

---

[†] Whilst the present paper was in the press, a review appeared by Prof. G. A. Wagner [10] of some recent German work upon this test. In the main, his conclusions are in agreement with our own.

UNITED STATES OF AMERICA.

(FROM AN OCCASIONAL CORRESPONDENT.)

Birth Control.

A NATIONAL campaign by birth control advocates was launched recently with a conference at Columbus, Ohio. The campaign has for its object the repeal of Federal legislation which now prohibits the use of the mails for any matter giving information on contraception or for the transport of contraceptive materials. The plan is to organise the country in four divisions carrying birth control propaganda into every State. The moving spirit of the conference was Mrs. Margaret Sangar who advocated control of conception under the following conditions: (1) to prevent the transmission of diseases to the new-born; (2) to prevent the birth of mentally deficient children; (3) to prevent illness, disability, and death among women who are physically unfit to bear children; (4) to prevent childbirth in adolescence; (5) to enable couples to regulate the size of their families in accordance with their economic means; and (6) to prevent births during the first two years of married life. The last recommendation is supposed to make it easier for married couples to make the psychological adjustments necessary in marriage. It must not be supposed that it would receive the approval of all supporters of the movement. Indeed, in the conference itself there were obvious disagreements about the purposes and consequences of birth control. One speaker regarded it as a cure for overcrowding and a prevention against war. Mrs. Sangar herself now takes the view, so strongly supported by Pearl's studies of population growth, that birth control does not mean limitation but selection of the population.

Fatal Automobile Accidents.

Early estimates of the total of deaths from automobile accidents during 1929 by the American Automobile Association reach the appalling figure of 27,000 deaths. This is greatly in excess of last year's mortality from the same cause. For the 52-week period ending Nov. 2nd the city death-rate is 25·6 per 100,000, compared with a rate of 22·1 per 100,000 a year ago. Camden, N.J., leads with a rate of 74 and Kansas City is at the bottom of the list with a rate of 10. The main cause of the increasing death-rate is probably the increasing congestion of traffic. The Automobile Association estimates that 2½ million cars will be added to the traffic during this year and make a total of approximately 27 million cars on the roads.

Overcrowded Prisons.

The extent of overcrowding in Federal and State prisons is emphasised in a recent statement by Paul W. Garrett, the editor of the "Handbook of American Prisons." He asserts that 124,783 prisoners are housed in buildings designed to hold only half that number. This "aggravates every problem of sanitation and puts an intolerable strain on the physical and mental health of every man so confined." The mistake made by many States as well as by the Federal Government is that they have passed new laws without making provision for the resulting increase in offenders. Perhaps the most serious result is the lack of means to offer employment to the luckless prisoners. The demoralising effect of this enforced idleness is obvious enough. That prison life may, on the other hand, afford excellent opportunities for reformatory medical work is shown in a report of Dr. Charles C. Sweet, the chief medical officer of Sing Sing Prison. This prison is fortunate in possessing a new hospital, a five-storey fireproof structure providing beds for 125 patients. A block of 88 cells attached to the hospital provides accommodation for chronic invalids. Sing Sing is a receiving prison whose inmates are soon transferred to other institutions. The medical staff do their best to send on the prisoners in better physical condition than when they arrive. More than 7000 injections of arsaphenamine have been given during the last fiscal year (positive Wassermann reactions are found in 12 per cent. of white prisoners and in 42 per cent. of the negro prisoners). Other needs are disclosed at the routine physical examination given to all prisoners on admission and the men are invited to submit to corrective treatment or sign a statement of refusal. In the past three years more than 90 per cent. have accepted the former alternative.

Cost of Medical Care.

Two years after its inception the Committee on the Cost of Medical Care has issued an interim report. At first glance it is rather a disappointing document. "The Committee . . . hopes that is may be possible to work out plans for the provision of adequate and efficient therapeutic and preventive treatment for all the people. . . . What plans will be developed the Committee does not know. After a year and a half of study, however, it believes that its investigation will define the difficulties of the present situation and will result in helpful recommendations." A somewhat undersized infant, one might say, after nearly two years of labour. Meanwhile, the State of New York is inaugurating a practical experiment which it is hoped may solve the problem locally, when the new public welfare law goes into effect at the beginning of the New Year. Whereas the old poor-law states that officials *may* give care in a hospital to an indigent sick person, the new public welfare law states that the official *shall* give any type of medical care needed, not only to completely destitute persons but also to "persons otherwise able to maintain themselves who cannot secure necessary medical care." The old law mentions care in a hospital, the new law care in the home, in a dispensary, hospital, or elsewhere. Illness need no longer be acute to arouse the interest and aid of the State. Prevention through early treatment of remediable defects is clearly envisaged. In this way the State may actually save expense as well as the lives of its citizens. To Englishmen it will perhaps not appear so very surprising that a State should recognise the maintenance of health as a proper public function, but in this country, where anything that savours in the least of "State medicine" is regarded with emotional horror by the great majority of physicians, the new law takes on an almost revolutionary significance.

A Medical Information Bureau.

It is now just over a year since the Medical Society of the County of New York and the New York Academy of Medicine jointly founded a medical information bureau. During the first year of its activity the bureau has sent out over a thousand letters and answered as many inquiries by telephones as by the post. The inquiries have come from all parts of the world and have been of the most diverse character. One inquirer had heard on the authority of "a doctor in England" that many women have their middle toes removed so that they may wear fashionable shoes and wanted to know whether the report was true or not. The bureau has been used by a number of organisations both commercial and philanthropic, including the Better Business Bureau and the newspapers. It is of interest to note that several of the larger advertising concerns have used the bureau as consultant in censorship. The bureau has also been active in "releasing" to the press statements concerning quackery and articles of popular health instruction. The bureau looks forward to increased activity and rapid growth in the coming year.

Public Health Services.

THE MINISTRY'S INSTRUCTIONS TO M.O.H.'S.

CIRCULAR 1048 of the Ministry of Health, issued on Dec. 5th of last year, indicates that the instructions to medical officers of health on drawing up their reports for 1929 are the same as for the previous year, except that reference to action under the statutory provisions repealed by the Nursing Homes Registration Act, 1927, is to be disregarded. The circular gives notice that in future the Registrar-General will furnish to all medical officers of health particulars of stillbirths by sex and legitimacy, and the medical officer is asked to include these particulars in his report. In the 1928 reports no general rule was observed. In some cases the registered stillbirths were given, in some cases the notified only, and in other cases there was no reference to stillbirths at all. In the past it has been our usual practice to discontinue comments on the annual reports after the close of the year of issue. The 1928 reports were, however, issued somewhat later in the year than usual owing, we understand, to pressure in the Registrar-General's office, which delayed the sending out of the usual statistical information to medical officers of health. We propose therefore to continue our comments on the 1928 reports for some issues in the new year.

REPORTS OF MEDICAL OFFICERS OF HEALTH.

TEN METROPOLITAN BOROUGHS.

THE following are some 1928 statistics of ten metropolitan boroughs :—

Name of borough and estimated (R.-G.) mid-year population.	Birth-rate.	Death-rates per 1000 of the population.					Death-rates per 1000 births.		
		All causes.	Tuberculosis.	Cancer.	Respiratory diseases with influenza.	Heart disease.	Infant and neonatal mortality.	Young child (1–5 yr.) mortality.	Maternal mortality from childbirth.
Chelsea .. .. (63,630)	12·6	13·5	1·19	2·00	1·6	3·1	49/16	27	3·7
Hackney .. (217,200)	16·0	11·7	0·85	1·56	1·8	2·1	67/27	27	4·3

Woolwich .. (141,100)	15·5	11·0	1·17	1·48	1·5	1·8	50/22	22	5·7

Relation of stillbirths to live births: Chelsea, 1·9 per cent.; Hackney, 3·7 per cent.; Hampstead, 3·6 per cent.; Islington, 2·5 per cent.; Poplar, 3·1 per cent.; Wandsworth, 2·0 per cent.; and Woolwich, 3·5 per cent.

Chelsea.

Dr. W. H. L. McCarthy's report shows that full use is made of the many voluntary agencies in the borough. Thus the Chelsea Health Society and School for Mothers, which employs four "part-time" medical women and a staff of health visitors, conducts the clinics and treatment centres in return for a subsidy of £750. Lady Melchett is the chairman of the committee, and she and Lord Melchett have purchased a large site adjoining the society's present premises with a view to erecting thereon a new maternity and child welfare centre. The tuberculosis dispensary is located at the Brompton Hospital, and the tuberculosis officer, Dr. W. J. Fenton, is one of the honorary physicians to the hospital. The borough council makes an annual grant of £1000 to the hospital and an additional payment of £160 for home visitation by the nurses. The borough council also subsidises the Nursing Association, the Day Nursing, and the Invalid Children's Aid Association, and has representation on the committees of these voluntary societies. Payments are made to the Ormond Maternity Home (six beds), the only institution of this kind in the borough, for the admission of necessitous maternity cases, and also to private midwives for domiciliary attendance, the net cost to the council for these services being £28 10*s.* 6*d.* for 1928.

Complaints of a serious nuisance from the emission of smoke and grit by the generating station of the London electric railways in Lot's-road gave rise to a conference and the promise of the installation of new boiler plant and suitable grit-arresters. Owing to the overflowing of the Thames on the night of Jan. 6th–7th, 33 basements and ground floors of inhabited premises were flooded, resulting in much hardship and distress, and the ruin of a large amount of furniture and household equipment. Energetic relief measures were adopted and no outbreak of disease was traced to the flood. An interesting survey of housing is given. A great part of Chelsea is comprised in the Cadogan and Sloane Stanley estates, and with the expiry of the leases the old type of small house has largely disappeared, and during the last 30 years some 18,000 Chelsea residents of the working and small trader class have had to migrate. Up to the war various trusts had however provided accommodation for 7000 persons of this type. Since the war the position has been more difficult for tenants of small means. The borough council has provided a block of 56 flats at a weekly rental, including hot water and electricity, of from 25*s.* to £1 14*s.* 3*d.* Two other schemes are in hand for the erection of working-class dwellings by the Guinness and Peabody Trusts respectively. Overcrowding exists mainly in the western district and has been little improved during the year. An effort is made to move overcrowded families to the housing estates of the County Council, 39 such families having been moved during the year, but in many cases the tenants object to being removed so far from their work. An improvement scheme known as "World's End Passage" in the western district has been approved and will result in the erection of 62 flats for 370 persons on the cleared site. There are a large number of houses let in lodgings with insufficient accommodation and conveniences for the several occupying families. Other problems are the dirty and destructive tenant and houses occupied by old people unable to look after themselves. It is hoped to deal with the latter under the L.C.C. Act, 1928, by removal to suitable institutions.

Hackney.

Dr. G. H. Dart mentions that a diphtheria immunisation clinic, conducted by Dr. F. J. Porter-Smith, has been opened. The work has proceeded smoothly, but it is thought that the education authority might give more assistance in making the clinic known. The certificates of immunity granted numbered 292 and 133 children were under treatment at the end of the year. Good results are claimed for the light treatment clinic by Dr. Dorothy Gere. The 111 cases treated included 30 of malnutrition, 11 of failure to gain weight without apparent cause, 21 of rickets, 9 of marasmus, and 8 of debility after acute illness. Dr. Dart considers that the restrictions put by the Ministry on the supply of nursing assistance and milk to mothers are unreasonable. He also describes the difficulty experienced in getting adequate repairs to dilapidated property carried out. The borough council have in hand the erection of 132 flats and 92 maisonettes.

Hampstead.

In 1925 it was estimated that some 2000 Hampstead families were living in an overcrowded condition. During 1928, as the result of the borough council's action, 110 families were moved to the L.C.C. estates at Wormholt and Watling, making with previous removals a total of 142. The inclusive weekly rents of the houses on the Wormholt estate varied from 14*s.* for a three-roomed flat to 21*s.* 6*d.* for a five-roomed cottage. The Watling rentals are somewhat higher. When a house has been vacated by such a removal, there is no power to prevent its being immediately overcrowded again, but only power to deal with the new overcrowding after it occurs. The borough council has, however, been most successful in preventing recurrence of overcrowding by getting into touch with the person responsible for the reletting of the vacated house. Nearly half of the total births (1001) occurred in hospitals or nursing homes. An analysis was made of the available housing accommodation in 340 of the 538 births which occurred at home. Of these 340 births—11·5 per cent. occurred in one-roomed tenements, 34·4 per cent. in two-roomed, and 40·9 per cent. in three-roomed. In three of the one-roomed tenements there were 5 occupants and in one 6 occupants before the birth. In one of the two-roomed tenements there were 8 occupants, in two 9 occupants, and in one 10 occupants prior to the birth of the baby. For the purpose of this investigation kitchens were counted as rooms, but not sculleries, bathrooms, &c. The borough council subscribes £1 for every Hampstead mother confined in Queen Charlotte's Hospital. The municipal prematernity clinic is conducted by a "part-time" lady doctor and was attended by 320 new cases.

Dr. Frank E. Scrase reports that the by-law made by the council as to the fouling of public footways by dogs on the lead came into force in September, 1927, and was well advertised, and that the council decided to take action against offenders reported during 1928. Convictions were obtained in four cases.

Islington.

Dr. G. Clark Trotter gives an instance where the notification of births proved a check on the accuracy of registration. A birth was registered and on investigation as to why it had not been notified, it was found that a woman had adopted a child and re-registered its birth as a child of her own and her husband, an absent seaman. The Registrar-General took proceedings and the woman was fined 10*s.* The maternity and child welfare work is conducted at four voluntary centres with a coördinating committee. The work includes antenatal, light, and dental clinics. One centre has a postnatal clinic where the mothers are examined six weeks after confinement. The balcony of the "west" centre was fitted with vitaglass during the year. An outbreak of small-pox in an Islington institution involved a large amount of work but did not affect the borough itself. In the investigation of puerperal fever the Metropolitan Asylums Board have provided facilities for the examination of swabs from persons attending the confinement. In one fatal case of puerperal sepsis a swab from the eye of the handywoman in attendance showed *Streptococcus viridans* and in another a swab from the septic finger of a handywoman showed hæmolytic streptococci and staphylococci. A summary from the "Dawes" report is given showing that Islington sends great quantities of refuse to dumps in Hertfordshire, and that the management of the tipping is much better conducted than formerly. A circular was sent to all dairymen in the borough asking them to prevent roundsmen from depositing broken glass in the roadway. Owing to complaints as to indifferent milk sold at the Dairy Show at the Agricultural Hall, the inspector went to a stall over which were two notices "Pure New Milk 2*d.* per glass" and "Milk with cream added 6*d.* per glass." A 2*d.* glass of milk was purchased and found to be deficient in fat 54 per cent.

The 37 cases of overcrowding dealt with during the year only represented a proportion of those encountered owing to the difficulty of finding other accommodation. Application was made to the L.C.C. for housing accommodation for 174 "special hardship" cases. During 1928 52 houses were demolished under a L.C.C. improvement scheme and 24 were converted into business premises. Successful prosecutions under the Sale of Food and Drugs Act included a considerable number for liniment of turpentine not in accordance with the B.P. standard and for prescriptions inaccurately dispensed.

Poplar.

Dr. W. Allan Young reports that the overflowing of the Thames affected 1141 houses and involved a large amount of work in the cleansing and disinfection of premises. The flood waters left behind a more or less offensive sludge. Floor boards had to be lifted, water pumped out from underneath, coal had to be supplied for drying, and lime and disinfectants were freely used. In July the flooding of 18 houses in North Bow by the blocking of a main sewer occurred and similar operations had to be carried out. In June a diphtheria immunisation clinic was opened at the new maternity and child welfare centre in Wellington-road, under the charge of Dr. F. J. Porter-Smith. At the close of the year 29 children had been immunised and at the time of writing the report the numbers attending for treatment had considerably increased. In reply to an inquiry from the metropolitan boroughs' standing joint committee on schemes for dealing with acute rheumatism in children, the Poplar Council considered that if a rheumatism supervisory centre could be established at one of the large general hospitals, with sufficient beds for several neighbouring boroughs and a convalescent hospital with education facilities could be established by the L.C.C. or M.A.B., coöperation between Poplar and adjoining boroughs in a scheme might be possible.

Child welfare work is divided between the borough council and the Royal College of St. Katharine. Dr. H. St. H. Vertue, the consulting physician of the municipal observation wards, shows that satisfactory and permanent results were obtained in most of the ill-thriving babies admitted. A children's consultation centre has been established at the London Hospital and during the year 16 cases from Poplar centres were referred to it. Antenatal work is steadily increasing and the popularity of the artificial light clinics with the mothers is shown by an increase in the attendances of 3678 over the 1927 figure to 10,128. For the first time on record there was no death from puerperal sepsis in Poplar. Dr. Harold Waller, the senior medical officer of the Royal College of St. Katharine, in his report deals with the campaign against the overclothing of children. He, of course, admits that artificial light treatment has its place and has served a useful rôle educationally, but he goes on to show with illustrations how much good can be achieved by natural sunlight and fresh air in a garden such as they have at the back of the College.

Southwark.

Dr. H. Wilson reports, as outstanding features of the past year, an outbreak of small-pox, which had not appeared in the borough for 20 years, and the holding of a most successful health week and exhibition. There were 19 cases of small-pox, mostly of the mild type, with one death. The housing problem is still acute and overcrowding can only be overcome by deportation. Many residents, however, object to being removed from a central position to a distance from their work and, if they do move, not infrequently return. During the year 133 families were moved to the L.C.C. estates. One slum area has been cleared and the preliminary steps with regard to a second are in progress. Sutherland House has been purchased for the maternity and child welfare scheme, and the work of two centres has been transferred there. Much antenatal work is done at Guy's Hospital and it is proposed to have special antenatal sessions at some of the municipal centres. The tuberculosis officer, Dr. J. T. Crowe, refers with satisfaction to the work done by the open-air schools for tuberculous children at Bermondsey and Clapham Common, and to the value of the L.C.C. scheme for the boarding out of the children of infectious tuberculous cases. He thinks the results of light treatment at Guy's Hospital, perhaps owing to poor food and indifferent homes, have not come up to expectations. This form of treatment will probably be discontinued but Finsen light treatment for lupus will go on. An important part of the health department work consists in the examination of food arriving at the wharves, and the certifying of food products exported to foreign countries. Considerable damage and inconvenience was inflicted by flooding at the north end of the borough and every assistance was given in the cleansing of premises and the drying of damaged belongings.

St. Marylebone.

Dr. Charles Porter mentions, as two noteworthy occurrences a small outbreak of small-pox (30 cases with no deaths) which was limited to St. Marylebone Home and Hospital, and the advancement of the Carlisle-street improvement scheme to a further stage. The area to be dealt with is the largest ever represented in the metropolis, covers 7 acres, and affects 340 premises and 2832 persons. The scheme now awaits the decision of the Ministry. Dr. Porter deplores the large number of registered food stalls in the market streets. The highways committee refuses registration when storage accommodation is unsatisfactory, and the necessary improvements cannot be carried out. Dr. Mabel Brodie has been appointed to conduct a diphtheria immunisation clinic and at the end of the year 60 children under 5 and 29 over 5 had been completely immunised. The public analyst, Mr. J. F. F. Rowland, would like to see a standard fixed for manufactured food products, such as lemon-cheese, which may now contain hardly any of the expected ingredients.

St. Pancras.

Dr. G. Sowden mentions that the borough council's Somers Town housing scheme reached a further stage, when the first block of 44 tenements was opened by H.R.H. Princess Mary on July 25th, 1928. Two further blocks of 44 flats are nearing completion. The weekly rents, inclusive of rates and water, are 13*s.* 7*d.* for a two-roomed tenement, 16*s.* 5*d.* for a three-roomed, and 18*s.* 8*d.* for a four-roomed. Each tenement includes a kitchen with gas cooker, copper, bath, sink, larder, and dresser. There is a shortage of housing accommodation for poorer persons with irregular employment or large families, and the housing provision made by the L.C.C. estates is beyond their reach. A cheaper house is urgently needed for such families, says Dr. Sowden, and should be centrally situated in order to lessen the cost of travelling to and from work. Dr. Sowden objects to the method of calculating maternal mortality from childbirth. The rate is given per 1000 live births, but is swollen by the inclusion of deaths incidental to pregnancy in its early stages. For example, of 33 cases of puerperal fever recorded in St. Pancras during 1928, only 22, and of five maternal deaths only two, followed the birth of a viable child. The remaining 11 cases and three deaths followed the occurrence of miscarriages, the total number of which is an unknown quantity. Further, one of the four deaths classified as puerperal sepsis was found on investigation to be due to procured abortion.

St. Pancras was visited by a severe epidemic of measles, which began in December, 1927. Measles is notifiable in St. Pancras, and for the first time during an epidemic preference was given to measles over scarlet fever, as regards admission to hospital. Dr. Sowden is disappointed with the results obtained but admits that statistics on a larger scale are necessary before any definite opinions can be expressed. Baldly, the results were as follows: 426 cases were admitted to M.A.B. hospitals and 33, or 7·7 per cent., died; 242 cases were admitted to Highgate Hospital, of whom 58 died, or 23·9 per cent.; while 2030 were nursed at home, of whom 24, or 0·8 per cent., died.

Wandsworth.

Dr. F. G. Caley says the residents of Wandsworth are fortunate in having 1202 acres of parks and open spaces in their area of 9190 acres, and also in having easy access to Wimbledon Common and Richmond Park. The council's obstetric consultant, Dr. Leonard Phillips, investigates any maternal deaths which present special difficulty. There were 88 cases of small-pox with no deaths, and in several instances persons actually suffering from small-pox were found following their usual occupations. At two diphtheria immunisation clinics, by the end of the year, 713 cases had been treated; 621 were negative on retesting and 92 were still positive when last tested. In three instances children, who had been treated but were not thoroughly immunised, had attacks of diphtheria so mild as to be negligible. Special arrangements had been made beforehand to deal with the usual biennial epidemic of measles. Measles is not notifiable in Wandsworth, but a successful effort to search out the cases at an early stage was made by close coöperation between the health visitors and school nurses, and eventually five temporary health visitors were engaged to deal with the epidemic. Nursing or admission to hospital when required were arranged for without delay. The cases found during the nine months of the epidemic numbered 4566, and the deaths during the same period were 38. This is a smaller fatality than in previous epidemics of similar magnitude. The number of cases removed to hospital was 236, but the case-fatality of the hospital-treated cases is not given. About 300 premises were affected by the Thames flooding. Energetic relief measures were adopted and 40 children from the area involved were sent into the country for a fortnight by the Children's Country Holiday Fund.

Woolwich.

Dr. J. Macmillan mentions as one of the important events of the year the opening of the Woolwich War Memorial Hospital. It is a general hospital with a small maternity section and an X ray electro-therapeutic department. The Woolwich Council have made capital contributions and reserve 12 beds for children under 5 years of age and accommodation for 66 maternity cases per annum. They have already provided for another 144 maternity cases at the British Hospital for Mothers and Babies. Both these hospitals have an antenatal clinic attended by the mothers who are to be admitted and both provide antenatal in-patient treatment when needed. The electrotherapeutist of the War Memorial Hospital, Dr. J. E. A. Lynham, conducts the municipal light clinic which was opened in October, 1927. He reports good results in debilitated children, marasmic babies, and rickets. Of 471 cases who have been under treatment, 177 are classed as much improved or cured, 80 as improved, 39 as stationary, 93 as still under treatment, and 73 as having ceased treatment. Dr. Lynham explains the large number who have abandoned treatment by the fact that at the beginning there was a boom and the mothers expected miracles, but on being disillusioned they found it inconvenient to attend, especially from a distance.

The Eltham housing estate of the borough council will be completely developed by the erection of another 142 houses. The estate covers 334 acres and will include 2178 houses, about half of brick and half of "Easiform" concrete. There are 1438 "A" houses with three bedrooms, 696 "B" houses with three reference to the occupation of the husband will be fully considered, though such supplementary tabulations cannot be undertaken until the completion of the census tabulations, which constitute in part the material required for their preparation. With regard to the second question, the matter will be very fully considered before the programme of supplementary tabulations is decided upon. But I may observe that it was not found advisable in 1921 to attempt any compilation of the mortality of the female population by reference to female occupations for the reason, among others, that approximately 10 per cent. only of the female population was returned as gainfully or industrially occupied.

Thames Floods and Public Health.

Sir KINGSLEY WOOD asked the Minister of Health whether he had any information as to the damage to health and property owing to the excessive Thames floods, particularly at Canning Town and the Tidal Basin areas; and whether he was taking any steps to consult the West Ham Council and other authorities with a view to the prevention and mitigation of such floods in the future.—Mr. GREENWOOD replied: I am not aware that there has been any flooding in the Canning Town and Tidal Basin areas during the recent abnormal weather conditions. The town council of West Ham have special powers with regard to the prevention of floods and the responsibility must rest with them, and with other authorities similarly situated, as to the extent to which such powers are exercised.

TUESDAY, DEC. 24TH.

Purchase of Radium.

Mr. MANDER asked the Minister of Health whether it was intended to restrict the purchase of radium from Radium-Belge to one firm; and, if so, the reason for that and for the exclusion of other firms.—Mr. GREENWOOD replied: I would remind the hon. Member that, as has already been stated in the House on more than one occasion, the Radium Trust are not appointed by me, but are constituted by Royal Charter. I am not in a position to anticipate any future decision which may be taken by the Trust on the matter referred to in the question.

Review of Service Pension Awards.

Sir GEORGE BOWYER asked the Minister of Pensions how many cases of ex-Service men's pensions had been reopened, although outside the time limit, during the last five months.—Mr. F. O. ROBERTS replied: About 180 fresh awards were made during the period referred to and, in addition, medical treatment was provided in some 60 cases of slight wound.

Regulation of Scottish Charities.

Sir GEORGE BERRY asked the Secretary for Scotland whether he proposed to initiate legislation, applicable to Scotland, to provide for the regulation of such charities as made an appeal for public support on the lines of the Collecting Charities (Regulation) Bill now before Parliament, and which was applicable to England and Wales only.—Mr. ADAMSON replied: I am considering the question of initiating legislation for Scotland on the lines of the Collecting Charities (Regulation) Bill relating to England and Wales now before Parliament, but in the present state of Parliamentary business there would, I fear, be little prospect of finding time this session for any such legislation.

Health of the Mercantile Marine.

Lieut.-Colonel FREMANTLE asked the President of the Board of Trade if the committee set up by his predecessor a year ago to advise the Board of Trade and the Ministry of Health on matters affecting the health of the mercantile marine had yet reported; whether the report would be published; and what action had been, or would be, taken to improve the conditions affecting the health of the crews and passengers concerned.—Mr. W. GRAHAM replied: The committee to which the hon. Member refers was set up to consider and advise on any questions affecting the health of the mercantile marine which the Board of Trade or the Ministry of Health might from time to time refer to them. The committee's advice on the various questions referred to it is submitted to the departments as its consideration of each subject is completed and no general report is published. The subjects with which the committee has already dealt include the Ship Captain's Medical Guide, which has been revised and issued, the Scales of Medicines and Medical Instruments and Stores for ships which do not carry surgeons, which also have been revised and issued, and the preparation of a code for facilitating medical consultation at sea by wireless telegraphy. This has been completed and forwarded to the International Code of Signals Committee. The subjects at present under consideration include an investigation of the statistics relating to the mortality of seamen and the hygiene of crew spaces on board ship.

Criminal Lunatics in Scotland.

The Duchess of ATHOLL asked the Secretary for Scotland the total number of convicted prisoners, Borstal inmates, and criminal lunatics in Scotland for the last three years for which figures were available and the number and percentage of these who were natives of the Irish Free State.—Mr. ADAMSON replied: The following table gives the information desired for the years 1926, 1927, 1928, so far as available:—

A = Convicted prisoners. B = Borstal inmates.
C = Criminal lunatics.

Year.	Total of persons received into custody during the year.		Irish nationality. Number* and percentage.
1926	A	15,685	3566 (22·7)
	B	126	21 (16·6)
	C	17	4 (23·5)
1927	A	14,839	3298 (22·2)
	B	139	18 (12·9)
	C	24	3 (12·5)
1928	A	14,737	3063 (20·8)
	B	140	13 (9·2)
	C	18	3 (16·7)

* The figures include persons born in the Irish Free State and Northern Ireland, and also persons born elsewhere if the father is Irish. Separate figures for Irish Free State cases are not available.

Grants for Poor Relief and Lunacy.

Mr. HURD asked the Secretary to the Treasury, in respect of each of the last five years for which figures were available, what were the sums paid by the Treasury to the county of Wiltshire by way of grants in aid of local taxation, showing separately the payments for poor relief and mental hospitals, and other purposes; and, in respect of the same period, the gross sums paid on these accounts to the counties of Hampshire and Berkshire respectively.—Mr. GREENWOOD replied: The following statement shows the amount of Government grants (excluding grants for capital purposes) received by local authorities in the undermentioned administrative counties in the year ending March 31st, 1928, distinguishing the purposes for which the grants were paid. The grants shown include, in addition to voted monies, grants out of the local taxation account and out of the road fund.

Administrative county.	For poor-law relief (excluding pauper lunatics).	For lunacy and mental deficiency.	For police, housing, public health, and all other services.
	£	£	£
Berkshire	12,139	7,614	181,184
Southampton ..	21,091	21,286	324,884
Wiltshire	19,490	17,724	253,945

The corresponding figures for earlier years are not readily available.

PAY-BEDS AT NEWCASTLE.—The governors of the Royal Victoria Infirmary, Newcastle-on-Tyne, have decided to utilise the three main pavilions in the Orthopædic Hospital for pay-beds. The decision is to a certain extent a consequence of the financial situation of the infirmary, the expenditure of the last ten months having exceeded the income by £11,416. The three pavilions will provide over 80 beds.

PROVINCIAL VOLUNTARY HOSPITALS IN 1928.—The tenth annual report of the Provincial Voluntary Hospitals of Great Britain for 1928 has just been issued by the Central Bureau of Hospital Information, with a preface by Mr. R. H. P. Orde, the director. The figures show that the in-patients had increased by 45,660 and the out-patients by 176,896. It is pointed out that, since each out-patient makes several attendances, these hospitals dealt with over 12,000,000 out-patients in the year. The total amount raised was £9,604,541, an increase of £900,473; the total expenditure on maintenance and development was £8,190,844 leaving a surplus of £1,413,697. The hospitals with a credit balance on their maintenance account numbered 598—78·79 per cent. The provincial voluntary hospitals pay about £100,000 a year in rates, and the assessments vary from zero to £20 per bed—there is no definite coördinated principle. The British Hospitals Association is taking such steps as lie in its power to have the matter considered by the proper authorities with a view to the removal of these anomalies.

EMPHYSEMA TREATED BY MECHANOTHERAPY.

To the Editor of THE LANCET.

SIR,—While admitting that mechanical measures may be of considerable help in certain pulmonary affections, I have no great faith in their value in cases of hypertrophous emphysema. In particular I do not think it advisable to attempt to reduce the size of the chest in this condition, nor indeed possible to succeed in the attempt without injury to this patient. In her communication to THE LANCET last week Dr. Kellgren-Cyriax refers to a patient, aged 73, "with undoubted emphysema." His chest was "barrel-shaped with the usual kyphosis. The chest wall was immobile, percussion note hyper-resonant, and breath sounds barely audible." The patient was treated "entirely on mechanotherapeutic lines, using chiefly passive and active exercise designed to strengthen expiration and in general to diminish the volume of the chest . . . . Treatment on these lines daily for a fortnight resulted in increased elasticity of the thorax, diminution of the barrel-shape and kyphosis, the breath sounds became more audible." While congratulating Dr. Kellgren-Cyriax on the patient's improvement under treatment, may I suggest that the attempt to reduce the size of the chest in a case of this kind implies a misapprehension of its pathology? The fact is, the enlargement of the chest in chronic hypertrophous emphysema is compensatory, an attempt on the part of Nature to minimise the evils resulting from a morbid condition. Owing to progressive loss of pulmonary elasticity the mean size of the chest undergoes a progressive increase owing to hyperactivity of the inspiratory muscles. Ultimately the barrel-shaped chest with kyphosis is produced in which the pulmonary capacity is greater than that which could be produced normally by the fullest possible inspiration. This process involves a fixation of the chest in the expanded position, the fixation being effected by a shortening of the chronically over-acting costal elevators (similar to the shortening which occurs in the muscles of the calf in talipes equinus), and by alterations in the costal joints and in the curves of the ribs. The enlarging thorax leads to a progressive tightening up of the elastic tissue in the alveolar walls which, owing to the loss of their elasticity, would otherwise become wrinkled, and thus encroach upon the alveolar cavities and in this way impede respiration. The fixation of the chest, while compensatory, is yet not an unmixed blessing, for while fixation saves the inspiratory muscles, it limits the expiratory movements and thus tends to render cough ineffective. We may be sure that the gain in the one case is greater than the loss in the other. While, during the advance of the disease, thoracic expansion progresses, costal breathing becomes correspondingly diminished and diaphragmatic breathing correspondingly increased; finally, costal breathing practically ceases and the breathing becomes entirely diaphragmatic, diaphragmatic expirations now being effected, not, as in normal subjects by elastic recoil only, but also by the vigorous contraction of the abdominal muscles.

These considerations lead me to conclude that, in estimating the effects of treatment on the dimensions and mobility of the patient's chest, Dr. Kellgren-Cyriax relied upon impressions rather than upon accurate measurement, since the enlargement of the chest in chronic emphysema is compensatory, the reduction of this man's chest even for a few minutes to the capacity proper to his early manhood would *inevitably lead to fatal asphyxia.*

I am, Sir, yours faithfully,

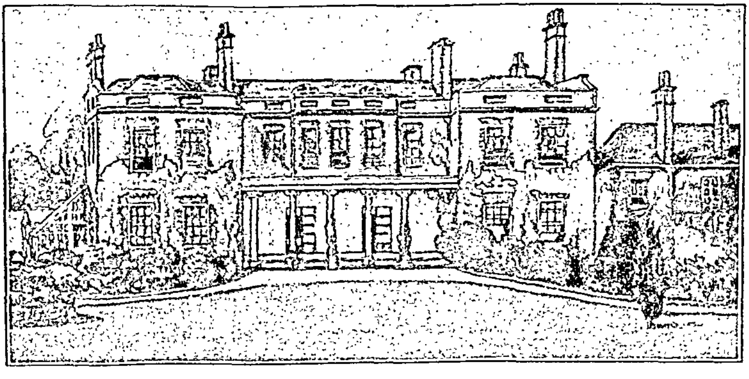
Harley-street, W., Dec. 28th, 1929. HARRY CAMPBELL.

UPTON HOUSE, PLAISTOW, THE BIRTHPLACE OF LORD LISTER.

To the Editor of THE LANCET.

SIR,—There are few now left who can remember Upton House, the birthplace of Lord Lister, as it was when his father, Joseph Jackson Lister, was living there. The main portion of the house still stands, shorn of some of its rooms and of the stables, and is the vicarage of St. Peter's, Upton Cross; faithfully are the associations with Lord Lister cherished by the vicar.

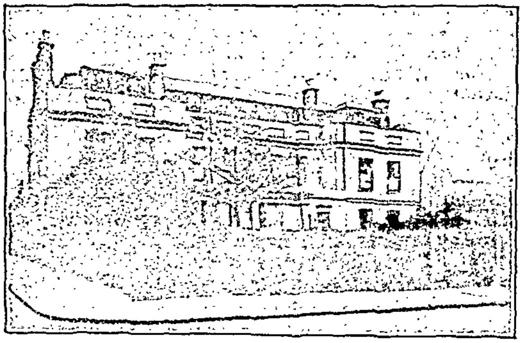
But the whole neighbourhood is completely changed, and what is now a densely populated London district was then hardly more than a country village. The beautiful garden at the back of the house has long been divided off and built over, but some of us remember the spacious lawn with its two great cedars, the kitchen garden beyond, the little summer-house, and the "terrace walk" with its broad holly hedge. It was over this hedge that the last wild red deer hunted from Hainault Forest bounded in 1828, and took refuge in the stable yard of Upton House. That was



Upton House as it was in Joseph Lister's childhood, after a drawing by Mary Lister. (From R. J. Godlee's "Lord Lister." Clarendon Press.)

when Joseph Lister was one year old. To the south of the garden was a meadow with scattered elms where cows grazed, and beyond were fields leading to the Thames Marshes.

There was a sense of peace about the old Georgian house and the grounds where the family of seven brothers and sisters spent their happy childhood. Besides the rooms usually occupied by the family there were attics where romps could take place undisturbed, and old lofts above the stables where tame owls and other pets were kept. Along the edge of the parapet the children would make their way round the roof, certainly without the knowledge of their elders. The study, with its French windows, seen under the colonnade to the left in the picture, was a sanctum where microscopic researches were carried on and grave converse held, and where children were only admitted by special permission.



Upton House as it now is. (From Handbook of Lister Centenary Exhibition at the Wellcome Historical Medical Museum.)

It was in the room above, the "Museum room," that in 1868 Joseph performed the operation of tying the carotid artery of a calf with a ligature made of catgut, the results of which proved the efficiency of seasoned catgut as a material for ligatures (see "Lord Lister" by Godlee, ed. 3, p. 229). The room with larger windows to the right was the old nursery, and behind it, facing Upton Lane, is the room where Joseph Lister was born in 1827, and where his father died in 1869. I am, Sir, yours faithfully,

Dec. 27th, 1929. G. LISTER.

*** An appeal for the preservation of the house which Miss Lister here describes has been issued over the signatures of the Bishops of Chelmsford and Barking, Lord Moynihan, and Sir James Slade, and with the support of Sir Humphry Rolleston, Sir William Lister, Sir StClair Thomson, and others. The house was purchased by the St. Albans diocesan authorities in 1885 and would have been sold by them on account of its dilapidated condition in 1918 had not the present vicar, the Rev. A. J. Parry, intervened and himself paid for the necessary structural repairs. A sum of £1800 it is stated would now capitalise the estimated annual dilapidations and preserve the house as the vicarage of the benefice. Should more money be subscribed the surplus would be used for setting up some memorial of Lister in the house itself. Cheques may be drawn in favour of "Lord Lister's Birthplace Preservation Fund," and sent to the hon. treasurers of the Fund at Upton House, Forest Gate, London, E.7.

Upton House, it may be recalled, is thus described in Dr. H. H. Bashford's "The Harley Street Calendar" (London: Constable and Co. 1929.), p. 209:—

> "Shorn of a wing and most of its garden, and the whole of the fields in which it stood, it is now the vicarage of an industrial parish, long since enveloped by the East of London. But at Lister's birth it was one of a little group of gracious and prosperous early eighteenth-century houses, surrounded by the farmlands of Thames-side, Essex, with the wild fowl nesting in Barking Marshes, and the panelled bedroom in which he was born looking westwards over Ham Park. This was the home—now an 'open space' carefully protected by Corporation railings—of his father's friend and fellow quaker, the Lombard-street banker, Samuel Gurney. And before the coming of the railway, when Lister was 12 years old—the fourth child in a family of seven—Mr. Lister and his neighbours, when the weather was fine, rode to their offices on horseback, or were collected by a coach, waiting at convenient points, and signalling its arrival by a horn."

—ED. L.

THE POSITION OF THE MEMBERS OF THE ROYAL COLLEGE OF SURGEONS OF ENGLAND.

To the Editor of THE LANCET.

SIR,—The position of the Members of the Royal College of Surgeons of England was set out clearly in your issue of Nov. 30th (p. 1149). A resolution advocating the representation of Members on the Council has now been passed by large majorities at 41 annual meetings of Fellows and Members. The reply of the Council to the resolution which was passed at the annual meeting of Nov. 21st last is given in your issue of Dec. 21st (p. 1341) when reporting the proceedings at the subsequent meeting of the Council of the College. In that reply the Council points out that no evidence is before them that any considerable number of Members desire a change in the constitution of the Corporation.

Now the only way to produce substantial evidence is to submit to the Council a widely signed request for consideration of a claim which everyone must admit to be just. A card of inquiry will accordingly shortly be issued to all Members and we trust that it will meet with a large response and that the position of the Members will be viewed broadly. At this stage the question of whether a Member is personally interested does not arise, for the whole body of Members are corporately interested in obtaining a recognition of their desire to be more intimately associated with the conduct of the College. Nor at this stage do any questions arise as to what measure of representation should be accorded and the machinery for securing it. All that is needed is an adequately large expression of the view that the desired modification in the constitution of the College should be brought about. We feel that the honour of the College is in question, and we confidently hope that this large view will be taken.

Financial help will be required to meet the expenses of the movement. We estimate that the sum of £250 will be needed and I shall be glad to receive subscriptions towards that total.

I am, Sir, yours faithfully,
ERNEST E. WARE,
President of the Society of Members, R.C.S.

60, Welbeck-street, London, W., Dec. 28th, 1929.

MUTILATING OPERATIONS.

To the Editor of THE LANCET.

SIR,—In your last issue Dr. F. G. Crookshank has written an interesting letter on mutilating operations from the psychological point of view. May I add some remarks from the surgical standpoint?

I am entirely in agreement with Dr. Crookshank's protest against the performance of unnecessary circumcisions. I have believed for many years that the word "phimosis" is much abused, and that only a small proportion of the circumcisions that are performed are surgically justified. I doubt whether adequate instruction is usually given to students on the subject; and I think that too often, at any rate in hospital practice, a ready-made diagnosis of phimosis is accepted without due consideration. Nearly always in the babies seen at hospital the mother complains that the baby screams when he passes his water or appears to strain. Sometimes this is due to acidity of the urine, and usually on examination the foreskin is found not to be narrow, but merely to have the normal adhesions to the glans;

at the worst a somewhat narrow preputial orifice can be rendered normal by a single stretching after the adhesions have been separated. Apart from psychological considerations against the performing of unnecessary circumcisions, the operation when performed upon babies in out-patient departments, as is usually done, is attended with serious dangers, and lives may occasionally be lost from post-operative hæmorrhage or sepsis. I have found in private practice that the simple operation of freeing adhesions and stretching the prepuce when necessary proves perfectly satisfactory, and is greatly preferred by most parents when the facts have been explained to them. I believe that the other arguments brought forward by Dr. Crookshank are of great importance, and that the operation of circumcision, when it has no ritual *significance*, should seldom be performed.

I am, Sir, yours faithfully,

GEOFFREY KEYNES.

Park-square West, Dec. 27th, 1929.

To the Editor of THE LANCET.

SIR,—I quake at my temerity in almost opposing Dr. F. G. Crookshank, but I think that some rather obvious data have been overlooked by him. Of course, quite unitalicised physicians and surgeons and laymen had already noticed neuroses and psychoses—though they may not have so labelled it—following on "unprovoked and unwarrantable trauma"; and with a sexual basis when the trauma had been genital. Moreover, male patients have been known who worried gravely over a relative inferiority in size of penis. The few of these who have consulted me were uncircumcised. Dr. Jago thought the cause of the Swahili's comparative ineptitude lay in the psychic changes induced by the physical trauma of circumcision in boyhood. Not very far off, however, were the Masai—circumcised before manhood. His white ruler and trembling black neighbours would not think it profitable to look for penile "organ inferiority" psychoses in the Masai. Age-long experience of Armenians, and Balkan Rayahs, of both sexes, did not disclose to them any sort of sense of any organ inferiority in the Ottoman Turk—circumcised in boyhood. We all, too, know of the vigorous tribes who cloud the north-west frontier of India. They are circumcised in boyhood; they have gained, nevertheless, a sense of humour. What a pity, then, that we shall not hear them on the sense of organ inferiority acquired by circumcision! Dr. Crookshank, however, has not made it clear enough whether he would consider all or any of these circumcised to have been subjected to "unprovoked and unwarrantable trauma." There is some slight suggestion in his letter that circumcision after infancy could be performed skilfully enough to keep outside his category of trauma unprovoked and unwarrantable.

There are the many, alive and for study, whose religion has enjoined circumcision in infancy. Outsiders have not yet noticed in them an undue proportion of sufferers from the sense of organ inferiority. And ready to Dr. Crookshank's hand are the Hebrew scriptures—surely extensive enough and naive enough material in which to look for signs of the sense of penile "organ inferiority."

Yet here again Dr. Crookshank is rather baffling; for with him circumcision in infancy seems to be "to strip a baby boy's penis." So it may be after all only a matter of operative technique and a too eager thoroughness. Metchnikoff—it is true of the school of Pasteur, Lister, and Koch, rather than of Freud, Jung, and Adler—saw in the prepuce and the hymen but evolutionary developmental faults, functioning no more than as obstacles to love. Sir Arthur Keith, of the school of Hunter, while agreeing as to the faults in development, cheered us all up by pointing out that love thrived on obstacles—perhaps a distinct approach to Dr. Crookshank's position.

I am, Sir, yours faithfully,

H. M. HANSCHELL.

Weymouth-street, London, W., Dec. 31st, 1929.

TREATMENT OF DRUG ADDICTS IN NEW YORK CITY.

To the Editor of THE LANCET.

SIR,—I read, with great interest, in your last issue the report of the Committee appointed in New York to investigate various methods of treatment for drug addiction. The experiments were carried out on a large scale, 100 patients being treated by each method tested. Narcosan, a much vaunted "specific," appeared to make symptoms worse and proved to be no specific. Treatment with various substitutes failed to relieve the patients and sudden and knock-out methods caused much suffering.

The gradual reduction method, attending to each symptom as it arose, involved the least suffering and proved to be the safest. This is the method I have always advocated, and I have employed it at Bay Mount for many years with success. In the hands of an experienced physician it can be administered in such a way that the patient does not suffer at all and experiences very little discomfort. In fact, patients are usually unaware when the drug is finally withdrawn.

If addicts could only realise that they can be treated without suffering they would present themselves more readily for treatment.

I am, Sir, yours faithfully,

STANFORD PARK, M.B., Ch.B.,
Resident Medical Superintendent, Bay Mount,
Paignton, S. Devon.

Dec. 28th, 1929.

COMPLICATIONS OF OPERATIONS FOR PILES.

To the Editor of THE LANCET.

SIR,—A perusal of the report of the meeting of the Proctological Section of the Royal Society of Medicine on the above subject in your last issue (p. 1360) makes me wonder more than ever why any surgeon nowadays recommends operations for cases of internal hæmorrhoids. For the past 15 years I and a few others in England, and a host of surgeons in America, have been pointing out that *every* case of uncomplicated internal hæmorrhoids can be cured with certainty and complete safety by means of injections—i.e., by a purely ambulatory treatment. This was true even before the high submucous injection of 5 per cent. phenol in vegetable oil had been described by me in 1928[1]—I believe for the first time in England; but it can now be added that by this method there is a complete absence of all serious complications, and that even pain is quite exceptional, whilst recurrences are at least as few as after operations of the old sort.

When one reads an appalling list of complications, like those mentioned at the meeting referred to above, one cannot help feeling that the discussion might almost have been designed as a text for the *advocates of the treatment by injection.* Every speaker at the meeting dwelt upon the impossibility of consistently avoiding the occurrence of very severe pain after operation, and there was considerable diversity of opinion as to the choice of method of operation with a view, firstly, to limiting the amount of pain; and, secondly, to limiting the incidence of cases of dangerous primary and secondary hæmorrhage and of severe stricture following operation. Mr. Milligan placed the incidence of the last of these as high as between 9·2 and 11·3 per cent.! Mr. Cecil Rowntree put the matter excellently when he said that "the patient who exchanged his piles for a stricture was reminded every day of his life what a bad bargain he had made." The same speaker referred to a fatality he had seen from intestinal obstruction following an operation for piles, whilst Mr. Norbury said that he had had two cases of suppurative pylephlebitis, one of which proved fatal. If experts like these have to admit such catastrophes and serious complications after their operations, one shivers to think what the mortality and morbidity-rates must be where less skilled operators are concerned.

---

[1] THE LANCET, 1928, i., 543.

Mr. W. B. Gabriel was the only surgeon at the meeting who so much as referred to the treatment by means of injection, and even he does not seem to have been very emphatic on his preference for that method. A possible explanation for his lukewarmness may be found on p. 1367 of the same issue, where he describes a syringe he has devised for "the high submucous injection of 5 per cent. phenol in vegetable oil as described by Albright and Blanchard." As his syringe holds only 3 c.cm. of oil, and as his needle is only 3¾ inches in length, it is evident that he has not grasped the essentials of Albright and Blanchard's method, because those American proctologists have laid stress upon the necessity of injecting very large amounts (from 2 to even 10 c.cm. into each puncture) and of going as high as there is any loose mucous membrane—if necessary even above the valves of Houston. The syringe described by Mr. Gabriel does not hold enough for even one injection and would not ever reach high enough—Blanchard at times uses a needle on a shaft some 7 inches long. Nevertheless, I welcome Mr. Gabriel as a convert to the treatment of internal hæmorrhoids by injection, even in cases of "bad piles." Mr. Gabriel wrote an invaluable article on the treatment of pruritus and of fissure by means of injection of anæsthesin in oil ("A.B.A.")[2] for which I have cause to be exceedingly grateful, because by his method I have now treated a large number of fissure cases without operation or general anæsthetics, and invariably with instant relief and—so far at any rate—without a single recurrence or mishap. This has made it possible to treat by injection even cases of internal hæmorrhoids complicated by fissure—cases which previously I should have dealt with by a preliminary divulsion of the sphincters under general anæsthesia.

Where so much can be done for rectal cases by "ambulant" methods it seems a thousand pities that the majority of rectal surgeons still continue to perform operations of the old sort, even though they admit the frequency and variety of severe complications and even occasional fatalities that they incur thereby.—I am, Sir, yours faithfully,

ARTHUR S. MORLEY.

Upper Wimpole-street, W., Dec. 28th, 1929.

THE BRUIT D'AIRAIN.

To the Editor of THE LANCET.

SIR,—Is it quite correct to say that the bruit d'airain was *first* described in April, 1857, and to suggest that it was not known to Laennec? (I am writing with allusion to the excellent paper by Drs. McLaughlin and Dix-Perkin in the last issue of THE LANCET.)

On reference to Gee's "Auscultation and Percussion"—that wonderful little book which constitutes an inexhaustible mine of information—I find it stated, on page 131, that the bell sound or metallic ring *was* well known to Laennec. Dr. Gee wrote, as do Drs. McLaughlin and Dix-Perkin, that coins are not necessary for the eliciting of this sound, and admitted that there is no reason for thinking that Laennec percussed with coins. But he cited the following passage from the "Traité de l'Auscultation médiate (i., 111, 696), which seems pretty conclusive:—

> "En auscultant à l'aide du stéthoscope, et percutant en même temps, on entend une résonnance semblable à celle d'un tonneau vide, et mêlée par moment de tintement."

On the other hand, Gee unhesitatingly accredits Trousseau with having given the name of bruit d'airain to the metallic sound heard, on auscultatory percussion, over a pneumothorax, sometimes at any rate, and irrespectively of the use of coins.

The authors of the paper in question have done such good work in helping us to get away from the notion that the metallic bell sound has any necessary connexion with the use of coins that I hope they will forgive me, not only for having raised the point that I have, but for making two more. (1) *Airain* is not translated by brass, but by *bronze*. Frenchmen always speak of what we call brass as *cuivre jaune*. (2) *Laennec* should be spelt always thus, as I have spelt it, without either vowel-ligature or diæresis, just as are the place names, Caen, Laon, &c.

I am, Sir, yours faithfully,

Dec. 28th, 1929. ANGLO-GALLICUS.

The Services.

ROYAL NAVAL MEDICAL SERVICE.

Surg. Rear-Admiral D. W. Hewitt is placed on the retd. list at his own request.

Surg. Capt. R. W. B. Hall to be Surg. Rear-Admiral.

W. M. Greer and J. G. Lynch to be Surg. Lts.

The following appointments are notified: Surg. Lt.-Comdr. (D.) C. Williams to *Pembroke* for R.N. Barracks, Chatham, and Surg. Lt. J. B. W. Rowe to *Peterel*.

ROYAL ARMY MEDICAL CORPS.

Col. G. G. Delap, late R.A.M.C., retires on retd. pay.

Lt.-Col. J. M. H. Conway, having attained the age for compulsory retirement, is placed on retd. pay.

Lt.-Col. W. P. MacArthur is granted the temporary rank of Col. while employed as Consulting Physician to the British Army.

Maj. L. C. Hayes retires on retd. pay and is re-employed.

Maj. B. L. Davis is placed on the half-pay list on account of ill-health.

ARMY DENTAL CORPS.

Capt. W. A. Rankin to be Maj.

MILITIA.

Maj. R. T. C. Robertson retires on attaining the age-limit and is granted the rank of Lt.-Col.

TERRITORIAL ARMY.

Capt. J. H. Iles, having attained the age-limit, relinquishes his commn. and retains his rank.

Lts. W. L. Kinnear, J. Carver, and C. D. Bruce to be Capts.

Second Lt. E. T. Colville (late R.G.A., Spec. Res.) to be Lt.

Supernumerary for Service with O.T.C.: Second Lt. W. P. Kennedy, from Gen. List, T.A., to be Lt., supern. for serv. with Med. Unit, Edinburgh Univ. Contgt., Sen. Div. O.T.C.

ROYAL AIR FORCE.

Flight Lt. G. Kinneir relinquishes his commn. on completion of service.

INDIAN MEDICAL SERVICE.

Capt. J. G. McCann to be Maj.

Lts. J. F. O. Bodman and B. N. Hajra to be Capts. (prov.).

Lt.-Col. W. G. Hamilton retires.

Fateh Mohammad Khan, Bishan Singh, and Madan Gopal Saincher to be Temp. Lts.

Temp. Capt. H. K. Datta, who has relinquished his temp. commn., is permitted to retain the rank of Capt.

The undermentioned officers relinquish their temp. commns.: Capt. C. Joshi and Lts. P. Singh, G. S. Malik, R. Lal, and K. T. Hosain.

REBUILDING OF PARIS FACULTY OF MEDICINE.—The Rockefeller Foundation has offered £1,200,000 towards rebuilding the medical school of the University of Paris. This school was built in 1877 to accommodate 1000 students, but now holds 5000. "It is well known," writes our Paris correspondent, "that the Faculty of Medicine, if rich in professors, has a dwelling only worth what the stones would fetch if it were knocked down. Many attempts have been made by Prof. Roger, dean since the war, to stir up the public authorities, and obtain the necessary money. But hitherto no success has been attained; the money did not seem ready to come. Now the Rockefeller Committee offers 6,000,000 dollars for the purpose, but only under certain conditions. Thus the new Faculty must be a whole block and must be built on a site near the present one and the Latin quarter. Such a site exists, but is at present occupied by the wholesale wine market. This, however, could be moved. The French Government will have to give an equal sum before the Rockefeller grant is made, but the general feeling of the press here is that this should be done so as not to miss the chance of making the Paris Faculty the finest in the world."

---

[2] Brit. Med. Jour., 1929, i., 1070.

Obituary.

COLL REGINALD MACDONALD, M.D. ABERD., D.P.H.

Dr. Coll Macdonald died in London, as the result of a street accident, on Christmas Eve, 1929, at the age of 77. He was a graduate of Aberdeen, and after a period of general practice in Ayrshire became county and district medical officer there in 1891. He was thus one of the first group of whole-time county medical officers in Scotland of whom there were 16 in all. Of these two are still in office, ten are dead, two are retired, and two transferred early to other appointments, one being still in active work. These appointments were all made under the powers of the Local Government (Scotland) Act, 1889. As an encouragement to the appointment of whole-time men, the Government of the day gave a grant of ten shillings in the pound for salaries and approved outlays. The majority of the counties decided in favour of whole-time men, and the county of Ayr, a large county with manufactures, mining, iron, shipping, and agriculture, went with the majority. Macdonald's main work in the early days was the promoting of hospital accommodation for infectious diseases. The large mining population demanded a great deal of sanitary supervision, and Macdonald was one of the five county medical officers asked by the Local Government Board for Scotland to make a report on the housing of miners as a preliminary to the later survey by the Royal Commission on housing. When the later developments supervened—medical inspection of schools, tuberculosis, child welfare, venereal disease, maternity service—Macdonald became head of the school health service, and took his full part in establishing this and the other sections of health work. The county and burgh authorities combined to take over the new sanatorium at Glenafton. They combined on a large scale also for child welfare, maternity, and venereal diseases, and in these four or five sections Ayr is one of the best organised counties in Scotland. By 1926, when he retired, Macdonald had a considerable staff under him for each of these main divisions of work. In the 35 years a soundly compacted county system of public health administration and school health administration had come into existence, and the new Local Government Act has had the way well prepared for it.

In person Dr. Macdonald was genial yet reserved. He was never wanting in appreciation of the work of his colleagues, and his own reports were sound and well proportioned. "His many friends will miss his sensitive conversation and his kindly smile," writes one who knew him personally.

THOMAS EVANS FRANCIS, O.B.E., M.D. LOND.

WE have to record the death at Colombo of Dr. T. E. Francis, at the early age of 47. Dr. Francis was last year obliged by ill-health to resign the post of medical officer of health for Barnsley, and his death occurred during a first voyage as ship surgeon. Born at Blackwood, in Monmouthshire, he was the son of George Gifford Francis and was educated at Pengam School and University College, Cardiff. From there he went to St. Mary's Hospital with an entrance Scholarship, subsequently studying also at St. Bartholomew's, and in 1905 he graduated as M.B. Lond. After a period as resident medical officer at Hampstead General Hospital he proceeded to the M.D. degree in State medicine and took up an appointment as assistant school medical officer for Glamorgan. In 1911 he became medical officer of health and school medical officer for Llanelly, but he left this work from 1914 to 1918 and served as a surgeon in the Royal Navy, being attached to *Britannia*, to the hospital ship *Soudan* and to the Haslar and Plymouth Hospitals. In 1920 he left Llanelly to fill the vacant post at Barnsley.

Dr. Francis married Beatrice, daughter of Edward Fisher, and his widow survives him with three children. His eldest son is studying medicine at St. Bartholomew's Hospital.

IN the obituary notice of Dr. Scott Riddell in our issue of Dec. 14th last Dr. Riddell's rank in the Order of the British Empire was wrongly stated. It should have been given as Commander.

Medical News.

UNIVERSITY OF CAMBRIDGE.—On Dec. 19th the following degrees were conferred:—

M.Chir.—F. J. Milward.
M.B. & B.Chir.—L. J. Rae.
M.B.—L. R. Janes and C. G. Townsend.

UNIVERSITY OF LONDON.—At recent examinations the following were successful:—

M.D.

Branch I. (Medicine).—Benjamin Barling, Univ. Coll. Hosp.; F. M. M. Eyton-Jones, St. Bart.'s. Hosp.; C. F. Fernando, Univ. Coll. Hosp.; T. R. Hill, Guy's Hosp.; B. B. Hosford, St. Bart.'s Hosp.; R. M. Maher, Univ. of Liverpool; H. L. Marriott, Middlesex Hosp.; R. L. Midgley and N. D. Patel, Univ. Coll. Hosp.; W. M. Ramsden, Guy's Hosp.; B. F. Russell and E. W. Skipper, London Hosp.; and E. C. Warner, Guy's Hosp.
Branch II. (Pathology.)—G. W. J. Bousfield, St. Thomas's Hosp.; Beatrice D. Pullinger and Dorothy M. Vaux, L.S.M.W.
Branch IV. (Midwifery and Diseases of Women.)—Janet I. Hoare, Winifred A. Ladds, and Edna I. Langston, L.S.M.W.; and Isabella L. H. Livingstone, King's Coll. Hosp.
Branch V. (State Medicine.)—G. L. Brocklehurst, St. Bart.'s Hosp.; and S. C. Gawne, Univ. of Liverpool.

M.S.

Branch I. (Surgery).—A. W. Holgate, Univ. Coll. Hosp.; and N. P. L. Lumb and R. W. Reid, St. Thomas's Hosp.
Branch III. (Ophthalmology.)—J. W. T. Thomas, Univ. Coll., Cardiff and Middlesex Hosp.
L.S.M.W. = London (Royal Free Hosp.) School of Medicine for Women.

SOCIETY OF APOTHECARIES OF LONDON.—At recent examinations the following candidates passed in the undermentioned subjects:—

Surgery.—J. S. Bury, Manchester; D. Ram Annamalai, London Hosp.; B. T. Squires, Guy's Hosp.; and C. D. Trimble, Birmingham.
Medicine.—C. W. Ellison, St. Bart.'s. Hosp.; V. J. Lopez, St. Mary's Hosp.; L. J. Pearson, Birmingham; T. G. Robinson and B. T. Squires, Guy's Hosp.
Forensic Medicine.—C. E. P. Davies and W. J. D'Rosario, Guy's Hosp.; R. J. Kagan, St. Mary's Hosp.; V. J. Lopez, Guy's Hosp.; D. Ram Annamalai, London Hosp.; and B. T. Squires, Guy's Hosp.
Midwifery.—T. Chandrasekharan, Madras; G. P. Charles, Sydney and Westminster Hosp.; W. J. Frith, London Hosp.; R. J. Kagan, St. Mary's Hosp.; I. W. H. Mansfield, Middlesex Hosp.; P. Somasunder, London Hosp.; L. J. P. Soromenho, Lisbon and St. Bart.'s. Hosp.; B. T. Squires, Guy's Hosp.; and C. D. Trimble, Birmingham.

The Diploma of the Society entitling them to practise medicine, surgery, and midwifery was granted to W. J. Frith, R. J. Kagan, V. J. Lopez, and B. T. Squires.

UNIVERSITY OF DURHAM.—On Dec. 21st the following degrees were conferred:—

M.D. (Practitioners of 15 Years' Standing.)—V. A. Goonetilleke and H. M. S. Turner.
M.B., B.S.—Abe Franklin, S. M. Garstein, C. M. Gillis, and J. L. Wolfe.

UNIVERSITY OF LIVERPOOL.—The late Prof. E. E. Glynn, formerly professor of pathology in the University, left £1000 for the department of pathology.

POST-GRADUATE COURSES IN NEUROLOGY.—A post-graduate course on Diseases of the Nervous System will be held at the National Hospital, Queen-square, London, W.C., from Feb. 3rd to March 28th. It will include 32 clinical lectures and demonstrations at 3.30 P.M. on each week-day except Wednesday and Saturday. There will be teaching in the out-patient department in the afternoons, and pathological demonstrations on Mondays at noon. Two other courses—on the Anatomy and Physiology of the Nervous System, and on Methods of Examination—will be given at noon on Fridays and at noon on Tuesdays and Thursdays. Particulars may be had from the secretary of the medical school at the hospital.

PHARMACEUTICAL SOCIETY OF GREAT BRITAIN.—At a meeting at 17, Bloomsbury-square, London, W.C. 1, on Tuesday, Jan. 14th, at 8.30 P.M., the Harrison Lectureship Medal will be presented to Mr. P. A. W. Self, who will deliver the Harrison Memorial Lecture upon Research. The Lectureship was established in memory of Colonel Edward Frank Harrison, Director of Chemical Warfare during the late war.

ROYAL INSTITUTE OF PUBLIC HEALTH.—The next congress of this institute will be held in Portsmouth during Whitsuntide, 1930, from Wednesday, June 4th, to Monday the 9th. The scientific work will be conducted in five sections: State medicine and municipal hygiene; naval, military and air (including tropical diseases); industrial hygiene; women and children and the public health; and tuberculosis. Further details may be had from the hon. secretaries at 37, Russell-square, London, W.C., 1.

RADIOLOGY AND TUBERCULOSIS.—The Joint Tuberculosis Council have arranged a post-graduate course to be held in the X ray department of the Hospital for Consumption and Diseases of the Chest, Brompton, London, S.W., from Monday, Jan. 27th, to Saturday, Feb. 2nd. It will be conducted by Dr. Stanley Melville, assisted by members of the hospital staff, and the class will be limited to 25 members who will form small groups. Further information may be had from Dr. William Brand, secretary of the Council, at Tavistock House North, Tavistock-square, London, W.C. 1.

UNIVERSITY OF BRISTOL.—Dr. R. J. Brocklehurst has been appointed to the chair of physiology in the University as from August 1st of this year.

A medical graduate of Oxford, where he took a first-class in the honours schools, Dr. Brocklehurst worked as assistant in physiology, first part-time, then whole-time, at St. Bartholomew's Medical College from 1925 to 1926. He was then awarded a Radcliffe Travelling Fellowship, with which he went to America and Germany. In August, 1928, he returned to take up the post of senior lecturer in physiology at University College.

DANGEROUS DRUGS REGULATIONS.—In pursuance of the Dangerous Drugs (Consolidation) Regulations, 1928, the Home Secretary has appointed two dental tribunals—one for England and Wales and one for Scotland—to which as occasion arises may be referred for examination and consideration any case in which there is, in his opinion, reason to think that a dentist may be administering any of the drugs to which the regulations apply, either to himself or to any other person otherwise than as required for purposes of dental treatment. The appointment of the tribunal is an extension to dentists of the system already adopted with regard to medical practitioners on the recommendation of the Departmental Committee on Morphine and Heroin Addiction in their report issued in January, 1926. The membership is as follows: England and Wales: Mr. W. H. Dolamore (chairman), nominated by the Dental Board of the United Kingdom; Mr. E. C. Sprawson, nominated by the General Medical Council; and Mr. N. G. Bennett, nominated by the British Dental Association, or Mr. F. Butterfield, nominated by the Incorporated Dental Association, with Mr. E. Percival Clarke, K.C., as Legal Assessor. Scotland: Mr. W. Guy (chairman), nominated by the Dental Board of the United Kingdom; Mr. J. H. Gibbs, nominated by the General Medical Council; and Mr. W. Graham Campbell, nominated by the British Dental Association or Mr. G. Hogg Patterson, nominated by the Incorporated Dental Association, with Mr. John Cowan, K.C., as Legal Assessor.

Medical Diary.

SOCIETIES.

ROYAL SOCIETY OF MEDICINE, 1, Wimpole-street, W.

TUESDAY, Jan. 7th.—8 P.M., TROPICAL DISEASES: PATHOLOGY. Special discussion on Tropical Diseases Arising from Dietetic Deficiency. Openers: Prof. J. W. B. Megaw (Tropical), Dr. G. Marshall Findlay (Pathology).

THURSDAY.—7.45 P.M., NEUROLOGY. Clinical Meeting at the West End Hospital for Nervous Diseases, Welbeck-street, W.

FRIDAY.—8.30 P.M., OPHTHALMOLOGY (Cases at 8 P.M.). Demonstration: Mr. F. W. Edridge-Green (introduced by Mr. Doyne): The Influence of the Parafoveal on the Foveal Region of the Retina. Papers: Mr. J. D. N. Cardell: Krukenberg's Spindles. Mr. E. Wolff: A Microphthalmic Family. Cases and Specimens: Mr. A. F. MacCallan: (1) Copper Wire in Eye—Specimen of Enucleated Eye. (2) Melanotic Sarcoma of Choroid. Other cases will be shown.

LECTURES, ADDRESSES, DEMONSTRATIONS, &c.

NORTH-EAST LONDON POST-GRADUATE COLLEGE, Prince of Wales's General Hospital, Tottenham, N.

MONDAY, Jan. 6th.—2.30 to 5 P.M.: Medical, Surgical, and Gynæcological Clinics. Operations.

TUESDAY.—2.30 to 5 P.M.: Medical, Surgical, Ear, Nose and Throat Clinics. Operations.

WEDNESDAY.—2.30 to 5 P.M.: Medical, Skin, and Eye Clinics. Operations.

THURSDAY.—11.30 A.M.: Dental Clinics. 2.30 to 5 P.M.: Medical, Surgical, Nose, Throat and Ear Clinics. Operations.

FRIDAY.—10.30 A.M.: Throat, Nose and Ear Clinics. 2.30 to 5 P.M.: Surgical, Medical, and Children's Diseases. Clinics. Operations.

WEST LONDON HOSPITAL POST-GRADUATE COLLEGE, Hammersmith, W.

MONDAY, Jan. 6th.—10 A.M., Dr. Dowling: Skin Department. 11 A.M., Mr. Tyrrell Gray: Surgical Wards. 2 P.M., Mr. Sinclair: Surgical Wards.

TUESDAY.—10 A.M., Medical Registrar: Medical Wards. 2 P.M., Mr. Hamblen Thomas: Throat, Nose, and Ear Dept. 2.30 P.M., Sir Henry Simson: Gynæcological Operations.

WEDNESDAY.—10 A.M., Dr. Burnford: Medical Wards. 2.30 P.M., Mr. Donald Armour: Surgical Wards. Dr. Scott Pinchin: Medical Out-patients.

THURSDAY.—11.30 A.M., Mr. Simmonds: Demonstration of Fractures. 2 P.M., Mr. Bishop Harman: Eye Department. 2 P.M., Mr. MacDonald: Genito-Urinary Department.

FRIDAY.—10 A.M., Dr. Pritchard: Medical Wards. 2 P.M., Mr. Vlasto: Throat, Nose, and Ear Department. 2 P.M., Mr. Sinclair: Operations.

SATURDAY.—9 A.M., Mr. Vlasto: Throat, Nose, and Ear Operations. 9.30 A.M., Dr. Burnford: Bacterial Therapy Department. 10 A.M., Dr. Owen: Medical Children's Department.

Daily, 10 A.M. to 5 P.M., Medical, Surgical and Special Out-patients, Operations, Ward Visits, Anæsthetic Courses.

ROYAL NORTHERN HOSPITAL, Holloway-road, N.

TUESDAY, Jan. 7th.—3.15 P.M., Dr. Rubens Wade: Anæsthesia.

EAST LONDON HOSPITAL FOR CHILDREN, Shadwell, E.

WEDNESDAY, Jan. 8th.—4.15 P.M., Clinical evening. Cases of interest will be demonstrated in the wards. Tea at 4 o'clock.

LONDON SCHOOL OF DERMATOLOGY, St. John's Hospital, 49, Leicester-square, W.C.

THURSDAY, Jan. 9th.—5 P.M., Dr. W. N. Goldsmith: Lichen Planus.

CENTRAL LONDON THROAT, NOSE, AND EAR HOSPITAL

FRIDAY, Jan. 10th.—4 P.M., Mr. N. Rankin: Ear-ache.

ST. MARY'S HOSPITALS, Manchester.

FRIDAY, Jan. 10th.—4.30 P.M. Post-graduate Lecture (at the Whitworth-street West Branch), Dr. W. Fletcher Shaw: Albuminuria and Eclampsia.

Appointments.

BARKER, M., L.R.C.P. Lond., M.R.C.S., D.P.H., has been appointed Deputy Medical Officer for East Ham.

BLANDY, M. A., M.B., B.S. Lond., M.R.C.P. Lond., Assistant Medical Officer, the Royal College of St. Katharine, Poplar Infant Welfare Centre.

GRIFFIN, A. J. B., M.B., B.Ch. Liverp., D.P.H., Medical Officer of Health for Worcester.

HUGHES, E. R., L.R.C.P. Lond., M.R.C.S., Medical Officer of Health for Holyhead.

POPPER, O., F.R.C.S., M.B., Ch.B. Edin., Surgeon in Charge of Ear, Nose, and Throat Department, Queen's Hospital for Children.

SPENCE, D. L., M.B., B.Ch'r. Camb., Medical Officer to the Post Office at Melksham Suboffice.

Glasgow Royal Maternity Hospital: M'CASH, MARGARET S. L., M.B., Ch.B. Glasg., and WILSON, ELIZABETH R. M., M.B., Ch.B. Glasg., House Surgeons; DOUGLAS, N., M.B., Ch.B. Glasg., and OSWALD, FRIEDA, J., M.B., Ch.B. Glasg., Outdoor House Surgeons.

Certifying Surgeons under the Factory and Workshop Acts: HASKINS, L.W. R., M.B., B.Ch. Dub. (Wadebridge, Cornwall); TURNER, J. W., L.R.C.P. Lond., M.R.C.S., (Berkhamsted); and WHITEHEAD, E. C., M.B. Lond., L.R.C.P. Lond., M.R.C.S. (Kings Cliffe, Northampton).

Vacancies.

Acton Hospital, W.—Res. M.O. £150.

Bethnal Green Hospital, E.—Sen. Asst. M.O. £500.

Birmingham, Dudley-road Hospital.—Gynæcologist and Obstetrician. £700.

Birmingham City.—M.O. for Maternity and Child Welfare. £600.

Birmingham City Mental Hospital.—Jun. Asst. M.O. £350.

Birmingham, Selly Oak Hospital.—Two Cas. O.'s. Each at rate of £200.

Blackburn and East Lancashire Royal Infirmary.—Res. H.P. £150.

Bloomsbury Dispensary, 12, Bloomsbury-street, W.C.—Res. M.O. £250.

Bradford Royal Infirmary.—Res. Surg. O. £250.

Brighton, Royal Sussex County Hospital.—Cas. H.S. £120.

Burnley, Victoria Hospital.—H.S. At rate of £125.

Cambridge, Papworth Village Settlement.—Second Asst. M.O. £350. Also H.P. At rate of £100.

Central London Throat, Nose, and Ear Hospital, Gray's Inn-road, W.C.—Hon. First Asst. in Out-patient Dept. Also Third Res. H.S. At rate of £75.

City of London Hospital for Diseases of Heart, &c., Victoria Park, E.—Anæsthetist.

Croydon General Hospital.—Hon. Gynæcologist and Hon. M.O.

Dreadnought Hospital, Greenwich.—H.P. and H.S. Each £110.

Great Yarmouth General Hospital.—Asst. M.O. to Ear, Nose, and Throat Dept.

Harrogate Infirmary.—Jun. H.S. At rate of £100.

Hospital for Consumption and Diseases of the Chest, Brompton, S.W.—H.P. £50.

Hospital for Sick Children, Great Ormond-street, W.C.—Part-time Jun. Cas. O. At rate of £150. Also Clin. Asst. M.O. for Venereal Dept. £1 1s. per session.

Huddersfield Royal Infirmary.—Jun. H.S. for Eye, Ear, Nose, and Throat Dept. At rate of £150.

Hull Royal Infirmary.—Third H.S. Also Asst. H.P. At rate of £150 and £130 respectively.

Ipswich, East Suffolk and Ipswich Hospital.—Cas. O. £150. Also first H.S. At rate of £120.

Leamington Spa, Warneford General Hospital.—Res. H.P. £165.

Leeds Jewish Herzl-Moser Hospital.—Res. M.O. £100.

Leicester Royal Infirmary.—Hon. Phys. and Hon. Surg.

Leigh Infirmary, Lancashire.—Res. H.S. At rate of £150.

Liverpool, Royal Southern Hospital.—Two H.P.'s. Three H.S.'s., and M.O. Each at rate of £60. Also Res. Cas. O. At rate of £100.

London County Council.—8th Asst. M.O. £300. Also Temporary Asst. M.O. 30s. per session.

London Female Lock Hospital, 283, Harrow-road, W.—H.S. At rate of £150. Also Hon. Obstet. Surg.

Manchester, Babies' Hospital, Burnage-lane, Levenshulme.—Sen. Res. M.O. At rate of £125.

Manchester Royal Infirmary.—Five H.S.'s. H.S. to Aural, &c. Four H.P.'s. All at rate of £50. Also Asst. M.O. and Clinical Asst. in Aural Out-patient Dept. Each £35.

Manchester, St. Mary's Hospitals.—Four H.S.'s. Each at rate of £50.

Manchester University.—Lecturer in Dental Histology. £50.

Metropolitan Asylums Board.—Jun. Asst. M.O. £500.

Mile End Hospital, Bancroft-road, Mile End, E.—Res. Deputy Med. Supt. £600.

Newark Hospital and Dispensary.—Res. H.S. At rate of £150.

Norwich City.—Asst. M.O.H. &c. £450.

Redruth, Cornwall, West Cornwall Miners' and Women's Hospital.—Res. M.O. £200.

Rochdale Infirmary and Dispensary.—Jun. H.S. £175.

Royal Army Medical Corps.—Commissions.

Royal Dental Hospital, Leicester-square, W.C.—Lecturer on Anæsthetics and Bacteriology.

Royal London Ophthalmic Hospital, City-road, E.C.—Out-patient Officer. £100.

St. John's Hospital, Lewisham, S.E.—Orthopædic Surg. Also Cas. O. At rate of £100.

Salford Royal Hospital.—H.S. At rate of £125.

Sheffield, Jessop Hospital for Women.—Two Asst. H.S.'s. Each at rate of £100.

Sheffield, Winter-street, Hospital.—Asst. Tuber. O. £450.

Southwark Metropolitan Borough, S.E.—Asst. M.O.H. £600.

Stafford, Staffordshire General Infirmary.—H.P. At rate of £150.

Stroud General Hospital, Glos.—H.S. At rate of £125.

Victoria Hospital for Children, Tite-street, Chelsea, S.W.—Sen. Res. M.O. At rate of £250. H.P. and H.S. Each at rate of £100. Also Out-patient Anæsthetist. 10s. 6d. per attendance.

West End Hospital for Nervous Diseases, Regent's Park, N.W.—Jun. H.P. At rate of £100.

West London Hospital, Hammersmith-road, W.—Asst. Dental. S. Also Two Hon. Anæsthetists.

Willesden General Hospital, N.W.—Res. H.S. At rate of £100.

Winchester, Royal Hampshire County Hospital.—Sen. Res. M.O. £200.

Wrexham and East Denbighshire War Memorial Hospital.—Two Res. H.S's. Each at rate of £150.

The Chief Inspector of Factories announces a vacancy for a Certifying Factory Surgeon at Faversham.

Births, Marriages, and Deaths.

BIRTHS.

THOMAS.—On Nov. 29th, 1929, at "San Remo," Belfast, to Elizabeth S. Thomas, M.B., B.Ch., D.T.H., wife of Captain A. F. F. Thomas—a daughter.

WILLCOCKS.—On Christmas Day, 1929, at Springfield, Chelmsford, the wife of Dr. R. W. Willcocks, of a daughter.

DEATHS.

DAVIS.—On Dec. 24th, 1929, suddenly, of pneumonia, at a nursing home in Eastbourne, Thomas Richard Earls Davis, M.B., Ch.M. (Sydney).

DUKE.—On Dec. 23rd, 1929, at Hyde-gardens, Eastbourne, Benjamin Duke, M.D., in his 84th year.

GRANT.—On Dec. 29th, 1929, after a short illness, at Kirkdale, Sydenham, William Francis Grant, M.D.

MACDONALD.—On Dec. 24th, 1929, suddenly, in London, as the result of an accident, Coll Reginald Macdonald, M.D., D.P.H., late County Medical Officer of Ayrshire.

RICHARDS.—On Dec. 23rd, 1929, at his residence, Grove-lane, Camberwell, S.E., G. W. Richards, M.D.

ROSE.—On Dec. 23rd, 1929, at Acocks Green, of pneumonia, Lauchlan Rose, M.A., M.D., late of Newport, Salop, and of Ministry of Pensions, Birmingham.

STUART.—On Dec. 29th, at a nursing home, after a short illness, James Stuart, M.A., M.B., C.M. Edin., of 92, Preston-road, Brighton, aged 73 years.

N.B.—A fee of 7s. 6d. is charged for the insertion of Notices of Births, Marriages, and Deaths.

Notes, Comments, and Abstracts.

TRAINING IN PREVENTIVE MEDICINE IN THE MEDICAL SCHOOLS.

BY ROBERT A. LYSTER, M.D., B.Sc., D.P.H.,
LECTURER IN PUBLIC HEALTH AND LECTURER IN MEDICAL JURISPRUDENCE AT ST. BARTHOLOMEW'S HOSPITAL; LATE MEDICAL OFFICER OF HEALTH FOR HAMPSHIRE.

FOR more than 25 years I have been engaged continuously in teaching public health and forensic medicine to undergraduates in medical schools, and also in the post-graduate teaching of qualified medical practitioners in training for the Diploma in Public Health. Over the same period I have been engaged in examining for medical degrees in various universities and for the D.P.H. It may, therefore, be claimed that I have had the advantage of viewing this subject from all sides, both as teacher and as examiner of graduates and undergraduates.

As a teacher for the D.P.H. I have met men who have taken their medical training in practically all the medical schools in the United Kingdom, and I have been struck particularly by two *important facts.*

1. The men taking the course had no common factor as regards their previous training in public health. Coming from different medical schools they had received varying amounts of instruction and those amounts represented different parts of the subject. It was dangerous to assume that even the majority of the class knew any particular branch of the subject to any degree.

2. In most instances the instruction they had received was completely inadequate even as an elementary introduction to the general principles of public health and preventive medicine.

During the period of 25 years covered by my experience two important changes have occurred. On the one hand, the medical curriculum has become more and more loaded with advanced clinical details which the ordinary practitioner may not be able to use in his practice, with the result that the instruction in public health and preventive medicine has never been allowed to expand and occupies, in fact, at the present time a somewhat smaller proportion of the medical curriculum than it did 25 years ago. On the other hand, the interest and knowledge of the public in this subject has increased by leaps and bounds, and we have at the present time a public thirsting for skilled guidance in health matters and in the practice of prevention.

The necessity for coördinating influences exists all through the medical curriculum. Even when learning the introductory sciences upon which medicine, and particularly preventive medicine, is founded the student gets into the habit of amassing facts and forgetting principles, and the tendency of the modern examination is to accentuate this danger instead of removing it.

He goes through his preliminary courses oblivious of the fact that, based on some of the simplest chemical, anatomical, and physiological facts, very important ideas concerning health and disease and its prevention may be founded. Even in *popular* elementary courses on this subject it is far more common to find this association and interest than in the introductory courses in the *medical schools.*

Isolation of Subjects.

Speaking generally, the various subjects are isolated from each other both in teaching and in examination, but the most marked isolation of all is reserved for public health and preventive medicine (and forensic medicine.) The creation of medical and surgical units in some schools has undoubtedly brought about a considerable degree of coördination in many ways and their existence should facilitate the introduction of "the preventive idea" into the whole curriculum.

In a lecture given at the Scientific Medical Conference held at the University of Rochester in October, 1926, Dr. Andrew Balfour, in speaking about the medical curriculum, said: "The student is *fortunate* if he gets more than an inkling of the huge subject of preventive medicine. He may, however, have an opportunity of grasping the cardinal facts that curative and preventive medicine cannot be divorced from one another, and that as a practitioner he will have duties both towards his patients and the State which it is imperative that he should fulfil to the best of his ability." Even this is sheer optimism.

The Average Practitioner.

The position is completely unsatisfactory. The practitioner of medicine is usually uninterested in and indifferent to all public health matters, and devotes himself to his sick patients, regarding preventive medicine as a job for someone else and in a few instances expressing hostile sentiments against those who practise it. His training has not been such as would be calculated to inspire him with any knowledge or interest or enthusiasm in the subject with which the general public is becoming more and more interested every year. Medical officers of health are trying to satisfy this demand for information by means of their schemes of public health propaganda, but the public appetite is very largely fed at present by the popular journalist, the stunt worker, and the sentimental fanatic, and the combined effect is deplorable. It is, in fact, difficult to exaggerate the serious character of the present position, with a public avid for health teaching on the one hand, and on the other a medical profession whose training, generally speaking, has not been such as to make it keenly interested or instructed in such matters.

In many of his writings the Chief Medical Officer of the Ministry of Health has dealt with the desirability of associating the general practitioner with preventive medicine, and has shown how easily the preventive idea could permeate the medical curriculum. So far as can be seen at present the result upon the teaching in the medical schools has been very small, and prevention is never likely to become a real part of the teaching in any medical school until a specialist teacher is appointed on the staff to deal with the subject and to press its claims.

The Medical Curriculum.

The fact is that the student is taught mainly the theory and practice of the diagnosis and treatment of diseased conditions, and that he receives little or no instruction upon prevention; he is launched into a course of instruction, investigation, and experiment which tends to concentrate attention almost entirely on treatment and cure rather than on the prevention of disease, while the study of the earliest signs of oncoming illness and the investigation of conditions leading up to it are liable to be passed over and neglected in the tremendous pressure of an overloaded syllabus.

The reason for this restricted condition of the curriculum is obvious. The training of the medical student at the present time is, for all practical purposes, entirely in the hands of eminent physicians and surgeons who have specialised in their particular departments, the result of whose excellent teaching is naturally to give the student the conviction that his life's work lies entirely among diseased persons. Such a state of affairs is inevitable under the existing arrangements in the medical schools, and it is not to be expected that the clinical teachers, who are experts in the treatment of diseased conditions, can alter their point of view and begin to teach prevention. Obviously, they must continue to teach their specialty—i.e., curative medicine and surgery. It is a matter of common knowledge that there are notable exceptional instances where a medical school is fortunate in possessing an eminent clinical teacher who is also an enthusiast in prevention, but such rare cases do not affect the general position.

The general practitioner is the main product of the medical schools, and if he is to take any important part in the prevention of disease in the future he must be taught prevention systematically and thoroughly as a student as part of an organised course in State and preventive medicine. His point of view needs to be altered, for instead of viewing the diseased portion of humanity as his special and only province, he should be expected to regard disease as something which ought to, and often could be, avoided. Such an altered point of view is not likley to be achieved without considerable innovations into the curriculum. A system which has for generations concentrated on the later stages is not likely, as the result of some small change in, or addition to a lecture syllabus, to pay sufficient attention to the investigation of predisposing conditions and the earliest stages of disease. In the interest of efficient teaching, in fact, it is necessary for each part of the instruction to be in the hands of experts—clinicians to teach diagnosis and treatment, together with investigations in those subjects, with experts in preventive medicine in charge of prevention and investigation into the factors leading to disease.

Teaching in Public Health.

All criticism and suggestions must be based upon facts concerning the present position in the medical schools of the country, and the following tabular statement has been prepared from returns made by the teachers concerned.

At St. Bartholomew's Hospital Medical College the combination of the course in public health with the course in forensic medicine under one lecturer enables the two to be dealt with as a course in "State and Preventive Medicine" occupying 30 lectures, and this arrangement has much to recommend it.

The table below shows that in the London Medical Schools the subject of public health and preventive medicine is officially allocated 12 hours of the medical curriculum. Assuming that the full medical curriculum occupies 4000 hours, the proportion occupied by public health is 0·3 per cent. In the English universities generally the attention given is substantially more, amounting to 30 hours, or 0·8 per cent., while in the Scottish universities the amount of time is *almost* doubled again, being 55 hours, or 1·4 per cent.

This subject has recently been considered by the American Medical Association in whose model curriculum the subject of public health and preventive medicine receives 3 to 4 per cent. of the entire medical course (roughly, 4000 hours) i.e., about 140 hours, so that even the Scottish universities have only travelled less than half-way towards the American model.

Hygiene and Public Health—Teaching in Medical Schools.

	Lectures of one hour.	Hours of practical work, demonstrations, &c.

Glasgow	50	5

The most obvious facts which appear to emerge from a consideration of the amount of instruction given to the subject of public health and preventive medicine in the medical schools at the present time are: (1) that a general levelling up in the subject of preventive medicine among the medical schools is necessary; (2) that a greatly improved position should be given to this subject as regards the time allotted to it in the ordinary medical curriculum. The advantages of such alterations would be obvious and immediate. The outstanding gain would be that the practitioner would take his proper place in the preventive system of the country, and he would be inclined to join sympathetically in the health education of the public in health matters, thereby displacing the stunt journalist and the quack from his present position. A matter of secondary advantage would be that the public health post-graduate courses would, moreover, receive a steady supply of qualified men thoroughly conversant with the general principles of public health and preventive medicine, and ready to take full advantage of more advanced teaching and also ready for instruction in practical administration. I propose to refer again to this point at the end of this paper.

Permeation of the Curriculum.

A memorandum on this subject which I prepared some ten years ago for the General Medical Council contains the following paragraph which might be quoted here:—

> It is suggested that the way in which preventive medicine could become a real live subject to the average practitioner is to introduce it properly into the medical curriculum, and the most suitable method, in conformity with modern developments, is by the creation of State Medicine Units in the medical schools. Such a unit would at first consist essentially of one professor only, with a standing similar to the professors of existing units, who would have charge of the teaching in State Medicine and who could act as a kind of "Liaison Officer" to the other parts of the curriculum on the subject of prevention.

The above suggestion is particularly interesting inasmuch as the experiment has since been carried out in the United States of America by the appointment of Prof. W. S. Leathers at the Vanderbilt University, Nashville, whose duty it is not only to carry out instruction in public health and State medicine, but also to secure as far as possible the permeation of the entire medical course with the preventive idea.

The preventive idea should permeate the *beginnings* of the medical curriculum at least as much as it should the later stages, and nothing is more calculated to arouse the interest of the student and to excite his lively attention than references to diseased conditions and their prevention, and the maintenance of health, during the courses in biology, physics, chemistry, physiology, and anatomy. All kinds of prophylactic ideas can be instilled in the mind of the student during his consideration of the chemistry of air and water. During the chemical course also toxicological matters can be introduced, while convenient opportunities can be taken to illuminate the subject with references to lime absorption by the body, dental hygiene, rickets, composition of foods, food value, and deficiency diseases. In fact, I have no hesitation in saying that, in a properly arranged curriculum, a medical student at the end of his second year ought to know far more about health and prevention of disease than he does about diseased conditions.

In connexion with the courses in anatomy and physiology there should be studied postures and the hygiene of the school classroom, exercises, eye-strain, many of the important points connected with industrial hygiene, hygiene of infancy, and all kinds of dietetic problems.

There is no need to refer to the obvious possibilities of introducing the preventive idea into the courses of bacteriology, pathology, medicine, and surgery. Ideas upon such a subject crowd into the mind which is accustomed to view medicine from the preventive side, but which are not likely to be carried out effectively unless there is in every medical school someone whose duty it is to look after this part of the training.

In an interesting paper published in the *Journal of the American Medical Association* Prof. Leathers discusses the importance of preventive medicine in the curriculum, and states the claim of preventive medicine and public health to be regarded as a major subject and department in the medical school. "There should be," he says, "in every medical school a department of preventive medicine and public health maintaining university standards in scope and ideals. Its scientific and professional status in the medical school will be weighed in comparison with the standards and development of the much older sciences of anatomy, physiology, and pathology, and others of the fundamental science group. With its present difficulties and handicaps it is much more difficult to gain the attention and maintain the consistent and sympathetic interest of the medical student in the hygienic and preventive aspects of medicine than in other branches of the curriculum. To offset this difficulty the place of preventive medicine in the medical school should be more definitely established, the regular and elective courses better defined, proper co-relation effected with clinical teaching, and its work integrated with the health services of the entire University."

At Vanderbilt University the regular course for fourth year medical students consists of 44 lectures and 66 hours of practical work, a total of 110 hours. Interesting interchanges are also arranged between the professors of preventive medicine and bacteriology, whereby the professor in preventive medicine deals with preventive items in the course of bacteriology, while the professor of bacteriology deals with that part of the course in preventive medicine which relates to the bacteriological examination of water and milk. Similarly, interchanges are arranged between preventive medicine and clinical medicine, and the remainder of Prof. Leathers's methods are best described in his own language when he says:—

> "In surgery, the control of cancer may be taught in the most graphic way. The prevention of venereal diseases and the social disease problem as a public menace can be discussed in gynæcology, obstetrics, genito-urinary and skin diseases. Child hygiene, including acute infections and problems related to nutrition, could be given special consideration in pediatrics, and maternal care in obstetrics; the prevention of blindness in ophthalmology. In the course of physiology, fatigue could be considered in relation to tuberculosis, and also the problem of nutrition affords a field for study in relation to health and disease."

Prof. Leathers concludes his interesting paper by quoting the impressive words of the late Dr. Sedgwick, who said:—

> "The medical school which fails to-day to provide also liberal instruction in preventive medicine, in vital statistics, in sanitary science, in public health laboratory methods, in epidemiology, in preventive sanitation, such as the sanitation of water-supplies and other branches of municipal sanitation; in preventive hygiene, such as mental, social, personal and dental hygiene; and in public health education and public health administration—that medical school *is sending out its graduates unprepared for* some of the most serious problems they will have to face in the immediate future."

Practical Proposals.

It is encouraging to note that these matters are now beginning to receive serious attention in many quarters. Recently the subject was discussed by the Southern Branch of the Society of Medical Officers of Health with the result that the following resolutions met with unanimous approval:—

> 1. The present system of medical training in this country is not such as is likely ever to produce in the average medical practitioner any real knowledge of, or liking for, or interest in preventive and State medicine. This lack of adequate instruction, moreover, is likely seriously to prejudice the supply of recruits for the health services of the country.
>
> 2. In view of the generally accepted opinion that preventive medicine can attain reasonable effectiveness only when the whole *medical profession* is trained in it, and takes an active part in its practice, and in view also of the fact that the interest of the *public* in preventive medicine has enormously increased recently, and is still increasing, it is desirable that efforts should be made forthwith in order to secure—
>
> (*a*) The establishment in all medical schools of a thorough and comprehensive course in State and preventive medicine as part of the ordinary medical curriculum, and associated with this course as its centre, the comprehensive infiltration of the whole of the medical curriculum with the preventive idea.
>
> (*b*) The requirement by the General Medical Council of proof of adequate instruction in preventive medicine before any candidate can proceed to any qualifying examination for a degree or diploma, and the requirement also by the G.M.C. of a special and adequate examination in this subject as part of all such *qualifying examinations.*

Much could be accomplished with the sympathetic coöperation of the examining bodies. At present the broad subject of preventive medicine is almost non-existent from an examination point of view, and the subject of public health receives but scant attention. The qualifying bodies in London do not treat it seriously, although the Society of Apothecaries grants it a share of a paper with forensic medicine, while London University gives it a half paper, and a viva voce examination shared also with medical jurisprudence. Similarly, the Scottish Conjoint Board and some of the English universities grant a half paper to the subject, but in the Scottish universities and some English ones it is raised to the dignity of a whole paper and a separate viva voce examination; in others it is combined with medicine. There is a clear case for levelling up and standardisation.

An Omen from America.

Under the English system the public health service can only be entered through ordinary medicine. In other words, the medical officer of health has, first of all, to become *a fully qualified practitioner and then he has to specialise* in public health in the form of post-graduate study. The advantages of this principle are, of course, obvious and need not be enlarged upon, but the fact remains that at present the number of entries into the public health training schools is at an alarmingly low ebb. It is therefore becoming increasingly obvious that in the public interest the medical student should have his interest stimulated in public health and preventive medicine and its ideals.

In America they appear to be trying an interesting experiment but one which has certain obvious dangers. Special schools of public health have been established which, although they include a large amount of ordinary medical curriculum, do not train students for a full medical qualification but award them, directly, a public health diploma which is, I understand, accepted as qualifying for the public health service.

I understand that the essential reason which led to this step—in my opinion, a very regrettable one—was that the number of men entering the public health service was insufficiently large, and a short cut, therefore, was devised owing to public demand. It is rather astonishing that the well-known business ability of the Americans did not try a more obvious expedient—i.e., making the public health service more attractive financially. I have been dismayed recently by certain figures which have been given me with regard to the remuneration of public health officers in the United States of America, and if these may be taken as representative of the whole service, then I am not at all surprised to hear that the number of well-qualified entrants is deplorably small.

The absolute necessity for the public health officer to be a completely qualified and even an unusually well-qualified man in general medicine and surgery is, I think, obvious to most of us. A public health officer can never be completely effective in his work unless his standing in the profession is such as will inspire respect from his professional brethren.

RESTRICTION OF LOCAL PRACTICE TO HOSPITAL Ex-R.M.O.'s.

THE medical staff of a provincial voluntary hospital asked the hospital committee to insert a clause in the conditions of appointment of the resident medical or surgical officer to the effect that he should not practise within a radius of ten miles for a period of three years after the termination of his appointment. The committee referred the matter to the Central Bureau of Hospital Information which sent out a questionaire to 51 hospitals, inquiring what was their attitude to the enforcement of such a restriction. At some of these hospitals there is one resident medical officer only; the remainder are larger hospitals, situated in industrial areas, county towns, and seaports, each with several resident medical officers.

Fifty-two replies were received, from which it appeared that in 44 (85 per cent.) of the hospitals there is no such restrictive clause in force or in contemplation. In one hospital of over 200 beds in an industrial town of over 100,000 population, there is no restriction at present, but the committee is considering making such a condition; it is stated that almost every house surgeon that has been at the hospital for the last six or seven years has afterwards settled down to practise in the town. Restrictions against practising in the hospital area are made when appointing resident medical officers at 7 out of the 52 hospitals, as follows :—

Hospital.	Number of beds.	Population of town.	Restriction against practising in the hospital area.	
			Not to practise within :	Period.
A	103	19,000	5 miles	6 months
B	96	62,000	10 ,,	5 years
C	95	46,000	5 ,,	5 ,,
D	62	26,000	5 ,,	5 ,,
E	58	37,000	5 ,,	3 ,,
F	56	23,000	10 ,,	3 ,,
G	45	40,000	2 ,,	Not stated

In the case of hospital G, the restriction is conditional, as follows: "Unless he shall have previously served as resident medical officer at the hospital for a period of not less than five years to the satisfaction of the Committee."

The following observations are extracted from the replies received from the hospitals where there is no such restriction.

(*a*) "Four house surgeons on leaving the hospital have set up for themselves here during the last 25 years."

(*b*) "In the past, many of our residents have practised in the neighbourhood and on many occasions have eventually become members of our honorary staff."

(*c*) "I have never heard of such a proposition and I consider it most unjust and think that such a step should be defeated, no matter who the medical staff are."

(*d*) "There are now three of our former house surgeons practising in our district and in each case they have gone into partnership with local practitioners."

(*e*) "No such clause exists in our appointments, and further, the committee does not agree that such a clause should be entertained."

The result of the inquiry appears as Memorandum No. 5 appended to the tenth annual report (for the year 1928) of the voluntary hospitals in Great Britain (excluding London), published by the Central Bureau of Hospital Organisation, 19, Berkeley-street, London, W.1.

NEW NURSERY FOODS.

We have received from the firm of Bickiepegs, Ltd., Welwyn Garden City, Herts, samples of three food preparations designed for the use of quite small children. The manufacturers inform us that they have been stimulated to produce these preparations by the writings of Dr. Harry Campbell and others who have laid stress in the medical press or at medical gatherings upon the value of proper mastication in the plastic formation of the tiny jaw and, thus, in the prevention of crowded teeth. The preparations consist of a vegetable broth to which veal bone-marrow has been added; some rusks of twice-baked bread, to which the name of "Chu-Chus" has been given; and some tiny little biscuits, "Bickiepegs," designed to meet a baby's need or desire, at the commencement of dentition, of something to bite upon. These minute biscuits are meant to take the place of the baby's fist, the corner of a shawl, or, indeed, any object to which a crawling baby can get access. These biscuits may well have a real use in assisting the proper eruption of the embedded teeth, where, unfortunately, an artificially nursed baby does not obtain the natural exercise afforded by breast feeding. The preparations have been produced under the direction of two well-known physicians, and the claims of good results that are made by the manufacturers would seem to rest on a sound basis.

SOME TRAVELS OF A VICTORIAN BIOLOGIST.

The late William Bateson, F.R.S., at the time a young man of 25 years of age, spent the years 1886-87 in biological research work in the Steppe. This was before there were any railway facilities in those parts and the author covered a large area of western Asia on horseback. His travels led him from the Aral Sea to Lake Balkhash, up the river Irtish to Omsk, and then westwards to Orenburg, due north of the Caspian Sea. Those who wish to know of the scientific results of the journey will find them recorded in papers in the Philosophical Transactions of the Royal Society. The letters that form the basis of the present volume[1] are those written to his mother and sisters at home, and were discovered after his mother's death in 1918, packed away in a trunk with other papers according to the fashion of hoarding correspondence which was a feature of the Victorian age useful to posterity. History repeats itself, for the author had trouble with the customs over the admission of scientific instruments into Russia. He gives a lurid picture of the art of packing a tarantass, which structure would appear to deserve his condemnation as one of the most unsatisfactory forms of carriage in existence. During his travels the natives were uniformly kind, though verminous, and the sole troubles that he had were with the authorities. At the start, in Petersburg, everyone was dilatory; he never got an opportunity of delivering a letter of introduction to a serenity, the Russian footman informing him that H.S.H. was not at home in a manner worthy of Jenkins Gruffanuff himself. His diet was that of the locality largely, and one would imagine that he never wished to taste mutton again. Some details of medical interest find a place among the letters; the results of small-pox were evident in many villages, skin diseases were common, as were ophthalmia and blindness. His servants were troublesome in the first year and unusually incompetent in the second. He suffered from diarrhoea and from a nasal discharge, acquired some veterinary skill in the treatment of sore backs, and did a great deal of temporary good to the villagers with a lotion of zinc sulphate. The book contains a couple of maps to illustrate the author's wanderings and a number of amusing drawings are printed in the margins of some of the earlier letters.

COD-LIVER OIL CREAM.

Our attention has been called to a cod-liver oil preparation made by Mr. R. Thomson, of Abbey-street, Elgin, Scotland, which has been highly commended by members of the medical profession who have used it. The emulsion is perfect and contains fresh eggs, 50 per cent. of a high grade cod-liver oil, and is newly prepared every week. In appearance it resembles dainty cream, is easy to take, and causes no unpleasant after-effects, while it is free from emulsifying agents which might affect the contents. We can recommend the preparation.

AN EXPERIMENT IN STERILISATION OF THE UNFIT.

The State of California has been carrying out, during the last twenty years, a vast eugenic experiment on the results of sterilisation of the mentally defective and unfit. We referred to the outstanding results of these investigations in our issue of May 14th.[1] In a little book[2] recently published, the gist of the pamphlets and papers scattered in various journals on this subject has been gathered together by Mr. E. S. Gosney, the philanthropist who has financed the inquiry, and Mr. Paul Popenoe, D.Sc., one of the leading eugenists concerned in it. The authors are convinced of the practicability and value of sterilisation under adequate safeguards, and their book is, of course, a piece of special pleading. It contains, however, many incontrovertible facts and should be read by everybody who is concerned at the alarming increase of mental deficiency in our country. The book goes to show that, in California at any rate, it is possible to sterilise large numbers of defective boys and girls without any appreciable risk to life, without any decrease in their happiness or usefulness, and without any of the alarming social consequences that are often threatened by the opponents of sterilisation. Appendices to the book contain a bibliography, an article by Dr. R. L. Dickenson on the surgery of sterilisation, a review of the sterilisation laws of the various States, the sterilisation figures in the various American institutions up to Jan. 1st of last year, and a review of a Roman Catholic discussion of the subject by Dr. Joseph Mayer. The book is published by the Human Betterment Foundation, a trust founded by Mr. Gosney in 1928 to perpetuate the work summarised in this volume and to endow similar social measures.

THE KOMFORT CORK SEAT.

We have received from Messrs. William Brookes and Co., sanitary seat-makers, 2, Royle-street, Oldham-road, Manchester, and 30, Langdale-avenue, Levenshulme, Manchester, a sample of a lavatory seat made of cork, stained, and covered with a varnish which is impermeable to fluids, so ensuring cleanliness. The seat has a low conductivity for heat and should therefore be comfortable for users who are sick.

A DISCLAIMER.

To the Editor of The Lancet.

Sir,—I should like it to be known that I had no knowledge of or participation in the notice of our work at the Bristol Royal Infirmary which has appeared in a lay journal.

I am, Sir, yours faithfully,

Bristol, Dec. 30th, 1929. A. T. Todd.

A Study
OF
RHEUMATIC DISEASE IN CHILDREN.

BY MAURICE CAMPBELL, M.D., F.R.C.P. LOND.,
ASSISTANT PHYSICIAN AND PHYSICIAN IN CHARGE OF THE CARDIOGRAPHIC DEPARTMENT, GUY'S HOSPITAL;
AND
E. C. WARNER, M.D., M.R.C.P. LOND.,
PHYSICIAN IN CHARGE OF THE CHILDREN'S DEPARTMENT, MILLER GENERAL HOSPITAL, AND MEDICAL REGISTRAR, GUY'S HOSPITAL.

RHEUMATIC disease in children is now receiving the attention that it deserves as the most crippling affection of the children of the poor. Committees appointed during the last few years by the British Medical Association[1] and by the Medical Research Council[2] have issued reports dealing with various aspects of the problem. With most of their conclusions we are in complete agreement; but we would reaffirm the importance of heredity as shown by the family history of rheumatism or chorea—a point to which they did not attach much weight—and we would at once emphasise one of our conclusions: that routine tonsillectomy offers little hope of reducing the high incidence of rheumatism. We have tried to deal with some of the factors predisposing to rheumatism—in particular tonsillitis and other infectious diseases—and rather more fully with the importance of tonsillar sepsis and tonsillectomy; with the time of year when attacks and relapses are most likely to occur; and finally with the incidence of temporary or permanent heart disease.

Our conclusions rest on a detailed study of 250 rheumatic children. These were drawn from a poor Thames-side district in South-East London, including the boroughs of Bermondsey, Southwark, and Lambeth, served by Guy's Hospital; and of Greenwich, Woolwich, Deptford, and Lewisham, served by the Miller General Hospital. Of these children, 180 were under the care of one of us (E. C. W.) as out-patients; and 70 were watched by one of us (J. M. H. C.), again as out-patients, after their return from Queen Mary's Hospital at Carshalton where they had been given a prolonged period of treatment in the country under ideal conditions. In view of the great expense involved and the tendency to extend such facilities in many areas, it is important to compare the end-results of such treatments. All these cases have been under our personal observation for at least six months and often for three years. In general, a fairly regular attendance in the out-patient departments has been maintained, and where attendances have temporarily lapsed the children have been asked to attend again through the agency of the Lady Almoner's Department, from which invaluable help and coöperation have been obtained.

THE INCIDENCE OF RHEUMATISM.

The children we have grouped as "rheumatic" were brought to the hospital on account of one or more of the following symptoms: (1) "growing-pains"; (2) pain and swelling in the larger joints of the body; (3) chorea; or (4) rheumatic carditis (usually first noticed at the school medical inspection). The following criteria have been adopted in classifying the patients in these groups:—

1. *Growing pains.*—In recent years there has been a tendency to regard as rheumatic all children who complain of aching in the legs, but this is not correct, and it is important to differentiate two groups of cases with pains of non-rheumatic origin. The first obvious non-rheumatic group is that in which there is an acute infection with a high temperature at the same time as the pains. It is often a simple tonsillitis, or may be almost any acute infection, especially influenza, pneumonia, scarlet fever, and diphtheria. In these cases the pains subside with the main disorder. The second group are debilitated children who suffer from aching legs. In addition to their limb pains, they have recurrent bouts of pyrexia, often with vomiting, nausea, or diarrhœa; vasomotor pallor; fatigue; irritability of temper, and loss of weight. They are under-nourished and have pale faces, often with dark rings under their eyes, and muscular hypotonia with all its consequences. These children have recently received attention, especially from Cameron,[3] Vining,[4] and Osman[5]; the condition from which they suffer is variously described as debility, hypoglycæmia, cyclical vomiting, or acidosis. It is not our purpose to discuss these children apart from their relation to rheumatic disease, but they frequently suffer from limb pains which are certainly not due to rheumatism. The distinction is usually straightforward, but is complicated when debility and rheumatism occur together.

The principal diagnostic points may be summarised as follows:—

(*a*) The limb pains of the debilitated child only occur in the legs, whereas true rheumatic pains affect the arms as well, though usually to a lesser extent.

(*b*) The pains of debility only occur during or immediately after exercise and disappear with rest, whereas the rheumatic pains occur at any time and are particularly noticeable at night. Thus it is only the rheumatic child who is kept awake with pain at night.

(*c*) The pains of debility are not true pains, but an "aching" or "feeling of tiredness" in the legs. Many rheumatic children, in addition to minor aches, have severe pains as well.

(*d*) In cases of doubt, the effect of treatment may be of value. The aching of the debilitated child usually responds to treatment by sugar or glucose.[3] [5] The pains of true rheumatism do not yield to this, but of course subside with adequate doses of salicylates.

2. Severe *joint pains* with high pyrexia—the classical acute rheumatism—have become rarer in recent years, and many "joint pains" are found on analysis to be extra-articular. But typical acute rheumatism is still very common, and when there is pain in many joints, perhaps with a collection of fluid, the diagnosis is easy.

3. *Sydenham's chorea* is now accepted as a special type of rheumatic infection. In early or mild cases it may be difficult to distinguish from habit spasms or the fidgety movements of a debilitated child. Only those children have been classified as choreic in whom there was unmistakable evidence of the disease.

4. *Rheumatic carditis.*—A few children came to the out-patient department for an acquired cardiac lesion which was thought to be rheumatic, although there was no other manifestation of rheumatism.

Including all the cases of acute rheumatism, rheumatic pains, chorea, or rheumatic carditis, the percentage of rheumatic children, compared with the total out-patients over the age of three, was about 15 (Table I).

TABLE I.

—	Cases of rheumatism.	Total cases above age of 3.	Percentage of rheumatic children.
Guy's Hospital ..	90	500 (to age of 10)	18·0
Miller " ..	70	510 (" " 12)	13·7

In addition to these 160 cases and the 70 children who had been in Carshalton with rheumatic fever or chorea, 20 older rheumatic children, seen at other out-patient departments, have been included. In most of our statistics, therefore, there are 250 cases, though sometimes the number quoted is less than this because full details were not available about all of them. Of these, 38 per cent. are males and 62 per cent. females, which bears out the common belief that rheumatic disease is more common in girls than in boys. The relative incidence of rheumatism, or chorea, or rheumatism and chorea (in the same patient, not necessarily at the same time), is shown in Table II.

The preponderance of girls compared with boys is seen in each of the subdivisions of the disease. While the sex preponderance for rheumatic pains is 1·2 to 1, that for chorea is 1·9 to 1, and that for chorea with rheumatic pains is 2·5 to 1 in favour of girls. This agrees with the accepted teaching on the subject.

TABLE II.

—	All cases.	Boys.	Girls.
	250	95	155
Rheumatic pains only	124	56	68
Chorea only	47	16	31
Chorea and rheumatic pains ..	75	21	54
Rheumatic carditis, but no history of rheumatism or chorea ..	4	2	2

HEREDITY IN RHEUMATISM.

The tendency of rheumatism to run in families is well known; it is of interest from an ætiological point of view to trace the frequency (Table III.)

TABLE III.

—	Cases.	Percentage with family history of rheumatism or chorea, in brothers, sisters, parents, uncles or aunts.
Rheumatic children ..	226	58
Non-rheumatic children	162	23·5

The table shows that 58 per cent. of rheumatic children give a family history of this condition in a near relative, as compared with 23·5 per cent. of non-rheumatic children. But while it is rare for a non-rheumatic child to give a history of more than one relative with rheumatism, it is extremely common for rheumatic children. Thus amongst this series we have one family where all four children have rheumatism, and another where three out of four children have rheumatism. It is also common to find that close relatives of rheumatic children have died of rheumatic heart disease in early or middle life. Children who have had chorea show a family history of rheumatism or chorea just as commonly as children who have had rheumatism only (Table IV., col. 3).

TABLE IV.

Children with—	Cases.	Percentage with a family history (in brothers, sisters, parents, uncles or aunts).		
		(1) of rheumatism but not of chorea.	(2) of chorea with or without rheumatism.	(3) of rheumatism or of chorea.
(a) Chorea only	45	26·5	33·5	60
(b) Chorea and rheumatism	64	23·5	28	51·5
(c) Rheumatism only	117	49·5	9·5	59

Columns 1 and 2 of this table show that a child who has a family history of chorea is much more likely to develop chorea as one of its rheumatic manifestations than if there were no such history. In other words, one of the chief factors concerned with the development of chorea is an inherited tendency.

THE AGE OF INCIDENCE.

The age at which the first symptoms occur has always been a striking feature, and is illustrated in Fig. 1. We have not included cases over 10, because so many of our patients have been taken from a children's out-patient department that it would not give a fair picture of the relationship of the periods 5–9 and 10–14, and still less of the older ages.

The disease is never seen in the first two years of life, and is extremely uncommon before the age of 4. The incidence reaches a maximum during the sixth and seventh years, and then begins to fall, though we have no comparable figures for adults. We have seen first attacks of typical chorea at the ages of 18 and 21 respectively, but this is uncommon. Chorea is not met with in this series under the age of 4, although there are eight cases of rheumatic pains starting before this. In fact, when we set out the number of cases of rheumatic pains and of chorea separately (Fig. 2) there are more cases of rheumatism in the early years of life than there are of chorea. It appears that the onset of chorea is first found when the child begins to fend for itself, and mix with other children in the streets and at school. Undoubtedly the mental strain of these factors is contributory to its first occurrence, and this is in keeping with the more generally recognised fact that the strain of school life and examinations is in part responsible for chorea in older children; this accounts for the increasing number of cases of chorea among the rheumatic manifestations at the ages of 7, 8, and 9 shown in Fig. 2.

Monthly Incidence of Rheumatism.

The time of year at which the attacks develop is of importance, and there is a general impression that more cases are seen in the winter. This is borne out by Fig. 3, which shows the months during which first attacks and recurrences are most likely to occur. It does not represent the month when they attend as out-patients, but in each case a careful history has been obtained as to the actual onset. The incidence rises sharply in September, and then gradually until a maximum is reached from November to April. From May to August there are many fewer attacks. In this series 135 attacks started in the four months from November to February, compared with 71 from May to August—a proportion of nearly 2 to 1. This monthly incidence is of importance in considering ætiology, and is probably related to the damp, cold atmosphere and the lack of sunlight and vitamins—all factors which undermine the health of the city child.

FIG. 1.

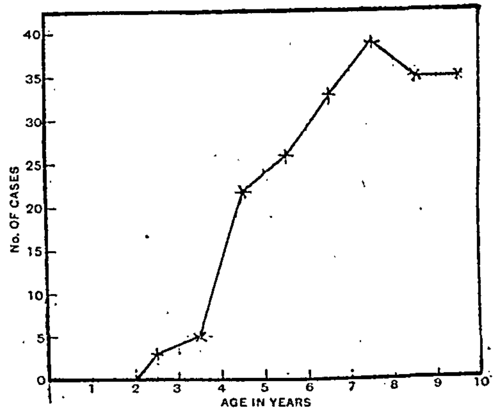

Chart showing incidence of rheumatism and chorea in children under 10.

COMMON SYMPTOMS PRECEDING RHEUMATISM.

In the absence of knowledge of the infecting agent, it is extremely important to maintain the child's health and resistance to infection; at present this is the angle from which the disease is being treated. We agree with Vining, who maintains that it is the debilitated child who develops rheumatism. We have not compiled statistics on this point as he has done,[4] but a series of common symptoms which have been complained of by the parents as occurring months or years before the first onset of rheumatism are: restlessness in sleep, night-terrors, unaccountable crying and bad temper, irritability, stammering, fainting, twitching and blinking, nocturnal enuresis, and loss of weight. The following are the notes of a typical case of a "debilitated child" who developed the first signs of rheumatism while under observation.

A boy, aged 8, was first seen in December, 1927, complaining of loss of weight and appetite for two years:

he had frequent headaches and colds in the head. He was a thin child, with rounded shoulders, poor muscular tone, and a few shotty glands in the neck. In January, 1928, he attended again and had by then developed typical rheumatic pains in his arms and legs, with mild choreiform movements and a soft apical murmur.

The child with "cyclical vomiting" is common in any out-patient department. Allied to cyclical vomiting are recurrent pyrexia and recurrent diarrhœa, and it is in this wide sense that we have grouped together children under the heading of "cyclical vomiting." It has been suggested that debilitated children are mostly of the cyclical vomiting type,[5] and are therefore liable to rheumatism. One strong argument against this is that cyclical vomiting is common among the middle and upper classes but rheumatism is very uncommon; it therefore appears that cyclical vomiting cannot be an important precursor of rheumatism. In 120 rheumatic children and 400 other unselected children, as shown by Table V., there was slightly more rheumatism in those with cyclical vomiting than in those without it, but the difference was hardly significant.

FIG. 2.

RELATIONS OF ACUTE INFECTIOUS FEVERS AND TONSILLITIS TO THE ONSET OF RHEUMATISM.

Any illness which lowers the resistance of a child may predispose to rheumatism, and it is commonly taught that diphtheria and scarlet fever are particularly likely to do this. In Table VI. are summarised the illnesses which immediately preceded the rheumatic manifestations: measles and scarlet fever were equally common. The other illness which so commonly occurs just before the onset of rheumatism is tonsillitis. The limb pains occurring with acute tonsillitis usually subside within three to four days and do not recur. Among those cases where rheumatism occurred after tonsillitis there was, in almost every case, a latent period between the subsidence of the tonsillitis and its accompanying pains, and the first rheumatic pains or signs of chorea. In this series of 250 cases there were 41 with related tonsillitis. Where the tonsillitis occurred about the same time as the original attack, the relationship is shown in Table VII. In 14 out of these 19 cases rheumatism started at least five days after the onset of the tonsillitis, and in another four it started soon after, without the exact interval being known. This is important from two points of view. In the first place, it militates against the idea that the infecting agent acquires an entrance with the initial tonsillitis, unless there is a long latent period; and, in the second place, from a prophylactic point of view it is wise to keep any rheumatic child away from school, and preferably in bed, for two weeks from the start of the tonsillitis.

HEART DISEASE IN RHEUMATISM.

The main importance of rheumatism is that it is so often accompanied by carditis. This may show itself in various ways, and the local signs in the heart fall naturally into three groups, according to the part of the heart affected. In this survey all cases have been observed for at least six months, and often for three years. It is common for a systolic murmur to be heard at the apex, especially at the height of the disease (43 per cent. of these out-patients; 69 per cent. of the in-patients from Carshalton). There were others in whom the first cardiac sound had lost definition, resulting in a "blurred first sound." Broadly speaking, there are two types of systolic murmur: (1) the soft, and (2) the harsher.

(1) The soft systolic murmur is more common, and in 44 of the 54 out-patient cases in which it occurred it ultimately disappeared. But it is almost the rule for this type of murmur to reappear with any severe relapse. It is difficult to assess the nature of the murmur when it is realised that rheumatism gives rise to inflammation of all parts of the heart. But its quality, its limited site at the apex, and its common association with an enlarged left ventricle, lead us to believe that the chief element in its production is the myocardial involvement.

(2) A harsher apical systolic murmur was met with in 11 out-patient cases, and in only four did it

disappear. This type is not localised to the apex, but is usually conducted to the axilla and up the left sternal margin. It therefore appears probable that the main factor in its production is mitral endocarditis. It is striking that this type of murmur should have disappeared completely in four cases, this disappearance being perhaps associated with a shrinkage of mitral vegetations and a greater elasticity of the mitral valve as the inflammatory exudate lessened.

In addition to the seven cases of a persistent harsh systolic murmur which developed while under observation, there were four cases with a soft systolic murmur which slowly developed into the harsher persistent and conducted murmur of mitral regurgitation. Murmurs were present in a much higher proportion of those who were treated as in-patients at Carshalton and a higher proportion were left with signs of mitral endocarditis. No doubt the higher incidence of murmurs was mainly due to the much more severe rheumatism or chorea, but partly to the fact that the patients were in bed under daily observation. As we personally did not see them at this stage we cannot make the same distinction as regards the type of murmur; but 69 per cent. developed a systolic murmur and about half of these were left with evidence of chronic changes in the endocardium of the mitral valves. In both groups there were a few patients who had signs of endocarditis when they first came under observation with fresh rheumatic symptoms (Table VIII.).

TABLE VIII.

Cardiac murmurs.	Out-patient series, 180 cases.	In-patient (Carshalton) series, 70 cases.

(b) Murmur harsh throughout	7	

Heart disease is more likely to occur in cases of rheumatism than in patients with chorea who have never had rheumatism (Table IX.).

TABLE IX.

—	Cases.	Percentage with carditis.
Rheumatic pains only ..	124	51
Rheumatism and chorea ..	75	56
Chorea only	47	34

Of the 47 cases of persistent mitral murmur (including the 18 of these who had developed it from earlier attacks of rheumatism) there were 18 who had signs of mitral stenosis. Two were only 6 years old, four were 8, and eight others were still under 14. Only seven had aortic incompetence. The youngest, aged 6, only gave a history of rheumatism during the previous six months, but the size of the heart and its X ray appearances made it certain that there had been rheumatic carditis of much longer standing. Three others had aortic incompetence when first seen, aged 10 to 14; they had suffered from rheumatic fever already, on an average for two years. One of these, aged 12, had aortic stenosis; he was 9 when he had his first attack, and aortic incompetence was diagnosed with his second attack when he was 11. In the last three, aged 8, 13, and 14 respectively, aortic incompetence was noted one or two years after the attack of rheumatic fever, in each case during a relapse which would otherwise have been called a minor one.

Enlargement of the heart, as demonstrated by the apex beat and percussion of its left border, may be a fallacious sign, because a forcibly beating apex, due perhaps to excitement or pyrexia, tends to come into a wider area of the chest wall and so gives an increased area of dullness. Bearing this in mind, and restricting the term "enlargement" to cases in which it was demonstrable on succeeding visits to hospital, it was found in 37 of the 180 out-patient cases; the extent is shown in Table X. The greater degrees of enlargement persisted in nearly half the cases, but the smaller degrees tended to disappear.

TABLE X.

Degree of enlargement of the heart to the left.	Cases.	Cases examined six months to three years later:—		
		Enlargement persisting.	Enlargement disappeared.	Doubtful.
(a) Half an inch and above	24	10	12	2
(b) Less than half an inch	13	2	10	1

Clinical evidence of pericarditis or adherent pericardium was recorded in only four of the out-patient cases, and in all of these the heart was seriously affected. One case was first brought to the out-patient department on account of numerous rheumatic nodules, and routine examination revealed their presence in three other cases. In our experience they have been uncommon in London during the last five years. There was erythema in nine cases; erythema nodosum in four, and erythema multiforme in two, while in the other three the rash was not seen but there was a history of erythema.

EFFECT OF PROLONGED INSTITUTIONAL TREATMENT AT CARSHALTON IN PREVENTING RELAPSES.

An attempt has been made to compare the results of the treatment at Carshalton (on an average for eight months) with those obtained in the group treated at home and as out-patients. A small number of these had occasional treatment in infirmaries or special heart-homes, but in them the average period of institutional treatment was short, and not to be compared with the better conditions at Carshalton. Both groups here are limited to those who attended as out-patients for at least a year, and the number with major and minor relapses was agreed upon by both of us when we worked through the records together. A minor relapse is indicated by "growing pains" of rheumatic type persisting for some days, or accompanied by a mouth temperature of 100° F., and a major relapse by a recurrence of acute arthritis, carditis, chorea, or prolonged and severe "growing pains." Adopting these criteria, the results are shown in Table XI. The number of relapses in the first three years was only half as many in the children

TABLE XI.

Period of observation.	Cases.		Major relapses.		Minor relapses.	
	Carshalton.	Out-patients.	Carshalton.	Out-patients.	Carshalton.	Out-patients.
First year	70	78	3	9	7	18
Second year (where there had been no relapses during first year)	51	32	5	9	6	7
Third year (where there had been no relapses during first two years)	20	11	2	3	2	2
Total	—	—	10	21	15	27

who went to Carshalton as in those who did not. This is all the more striking when it is realised that originally they were more severe cases with a higher incidence of permanent heart disease, and so should be more likely to show relapses.

Apart from these definite relapses, there is the difficult question of deciding when an attack has really come to an end, particularly as rheumatic carditis may continue without any obvious pains. In any child with active rheumatism it is common to find pyrexia and a raised pulse-rate, and recently Bourne [6] has stressed their importance as evidence of active disease. We have the temperature and pulse-rate of every rheumatic child taken at each visit, and though occasionally there may be slight pyrexia and tachycardia due to excitement, this can be excluded if the temperature and pulse be taken by a district nurse in the patient's own home for a few days. Otherwise a persistent mouth temperature above 100° F., after all other symptoms and signs of active rheumatism have disappeared, generally means active or smouldering disease, and needs treatment. As the active disease subsides, so does the temperature, usually to 98° F. This pyrexia, and the pains, may be masked if salicylates are given, and as there is no evidence that they have any beneficial effects once the acute pains have subsided we make it a rule never to give them to an out-patient after the acute phase. Even in the absence of pyrexia, tachycardia—e.g., in a child of 10–12 years a pulse-rate above 100—persisting after the acute symptoms have subsided is in many cases due to a smouldering carditis, of which there may be no other evidence. Most children have sinus arrhythmia during health, and a return of this usually means a subsidence of acute rheumatism.

THE TONSILS IN RHEUMATIC AND NON-RHEUMATIC CHILDREN.

There are such conflicting opinions about the importance of tonsillar sepsis in rheumatism that a special study has been made of this problem. The proportion of rheumatic and non-rheumatic children who give a history of one or more attacks of tonsillitis is the same (Table XII.).

TABLE XII.

—	Cases.	Percentage with history of tonsillitis.
Rheumatic children ..	166	58·4
Non-rheumatic " ..	250	58·0

Another method of investigating this relationship is to compare the tonsils of rheumatic and non-rheumatic cases. It is difficult to define what is meant by septic tonsils, but the points considered were the degree of redness, the superficial scarring, the presence of large red granulations projecting from the surface, and the amount of debris in the crypts. These criteria apply equally to the tonsils of both groups, and the results, set out in Table XIII., show no significant difference between the two sets of children.

TABLE XIII.

—	Cases.	Percentage distribution according to condition of tonsils.		
		Very septic.	Septic.	Doubtful or not septic.
Rheumatic children ..	145*	6	45	48
Non-rheumatic " ..	412*	5	48	46

* See footnote to Table XIV.

A method of assessing the degree of septic absorption from the tonsils is by measuring the size of the tonsillar group of lymphatic glands. This is less subject to the personal equation of the observer than estimating the degree of sepsis of the tonsils themselves, and is perhaps more reliable. Applying this classification to the rheumatic and non-rheumatic children, we get the results shown in Table XIV. If there is any significant difference, the size of the tonsillar glands is less in the rheumatic children.

TABLE XIV.

—	Cases.	Percentage distribution according to size of tonsillar glands.			
		Very large.	En-larged.	Readily palpable.	Not readily palpable.
Rheumatic children*	145	9	40	38	13
Non-rheumatic " *	284	14	49	25	12

* Tonsillectomised children are excluded from both groups.

The influence of tonsillar sepsis may be summarised by saying that the tonsils are not more septic, and that the degree of septic absorption (as judged by the size of the tonsillar lymph glands) is rather less in the rheumatic than in the non-rheumatic group.

Influence of Tonsillectomy on the Subsequent Onset of a First Attack of Rheumatism.

Many enthusiasts claim that tonsillectomy would have prevented the first manifestations of rheumatism, but our statistics do not support this view. The term tonsillectomy has been restricted to patients whose tonsillar bed was completely free of all remnants. Cases in which the removal was incomplete are considered separately. The non-rheumatic children are fair as a control group of the population in the hospital neighbourhood, as the majority attend for minor ailments (such as common colds). In each of the children who developed rheumatism a careful history was taken to be sure that complete removal of the tonsils took place before the first manifestation of rheumatism. These results are expressed in Table XV.

TABLE XV.

—	Cases.	Percentage who subsequently developed rheumatism.
Children with complete tonsillectomy*	124	15·3
Children whose throats have never been operated upon*	843	15·6
Children with incomplete tonsillectomy	43	32·5

* The average time elapsing between tonsillectomy and the development of rheumatism was just under two years; the average time between tonsillectomy and the first attendance of the non-rheumatic children at the out-patient department was the same, so that the figures are quite comparable.

Complete enucleation of the tonsils is without effect in preventing the onset of rheumatism, the proportion of children who subsequently develop rheumatism being the same as if the tonsils had not been enucleated. But the series of children with an incomplete tonsillectomy before the onset of rheumatism shows a much greater tendency to develop rheumatism. As this group comprises 25 per cent. of the cases with a tonsillar operation it is a sufficient justification for insisting that this operation shall always be done by skilled hands, so that the enucleation is complete.

Of the 24 children who had tonsillectomy before the onset of rheumatism, 14 developed chorea and 10 developed rheumatic pains in their first attack; the *first* manifestation is therefore more commonly chorea than rheumatic pains. This is contrary to what happens in non-tonsillectomised children, and agrees with the findings of the Medical Research Council Report [2] that in *recurrent* attacks after tonsillectomy, chorea is more likely to be met with than if tonsillectomy had not been performed. In view of the possible relations of diseased tonsils to rheumatic heart disease we are summarising this investigation with reference to tonsillar sepsis in non-rheumatic children, and in rheumatic children without cardiac involvement, with temporary cardiac involvement, and with permanent cardiac involvement (Table XVII.). There is no evidence that there is any relationship between tonsillar sepsis and the development of temporary or permanent carditis. It is important to see whether complete tonsillectomy before the onset of rheumatism causes the heart to be spared when rheumatism develops. The results are shown in Table XVIII., and there is no evidence at all that the heart is spared. Contrary to the suggestion of Reginald Miller,[1] tonsillectomy is no more use as a prophylactic against the heart becoming involved in cases of rheumatic fever than in cases of chorea. Actually in our series the highest percentage developing carditis was among the choreic children whose tonsils had been removed earlier.

* The term carditis is used where an organic systolic murmur was present (76 cases), and in cases with at least half an inch enlargement of the left ventricle beyond the nipple line (seven cases).

SUMMARY AND CONCLUSIONS.

Rheumatism occurs so frequently in the children of the poor that 15 per cent. of these above the age of 3 attending two hospitals in South-East London attend for this disease. Our impression is that the poorest are the most commonly affected, and it is certainly as common in them as in children of the artisan class. This is contrary to the findings of the Reports of the Medical Research Council and the British Medical Association.[1,2]

Among these 250 cases three girls are affected for every two boys, and this sex preponderance is more marked in chorea. Rheumatism rarely occurs before the age of 4, and chorea rather later. The commonest age for the onset is 6 or 7 years, after which there is a slight decline. But later chorea forms a larger proportion, probably owing to the strain of life at school.

A family history of rheumatism occurred in nearly 60 per cent. of these cases, but in only just over 20 per cent. of some non-rheumatic controls; it is therefore an important ætiological factor. Further, it has an influence in determining which rheumatic manifestation is likely to occur, for chorea was found more often where there was a family history of chorea.

An attack of rheumatism is more likely to start during the winter months from November to April.

One of the most important factors predisposing to rheumatism is a debility. Thus an attack often follows the specific fevers—e.g., measles or scarlet fever. "Cyclical vomiting" is of little importance in this respect.

In the same way tonsillitis may predispose to rheumatism. In almost every case in this series, where there was a history of related tonsillitis, there was a latent period of from several days to three to four weeks. If the infecting organism gains an entrance during the attack of tonsillitis this is contrary to the idea that it is a streptococcus. Children who have once had rheumatism should be kept indoors for at least two weeks after tonsillitis.

A systolic murmur was heard during the height of the illness in about half these patients, and was much less common in chorea than in other cases of rheumatism. Permanent signs of heart disease remained in 15 per cent. of the "out-patients" and in 30 per cent. of those who had been treated as in-patients at Carshalton, obviously because these had suffered from much more severe attacks of rheumatism or chorea. In spite of this there were only about half the number of relapses among those patients who had been given a long course of institutional treatment at Carshalton.

There is no evidence that the tonsils of rheumatic children are more septic than those of non-rheumatic children attending as out-patients. The frequency of tonsillitis, the septic appearance of the tonsils, and the degree of enlargement of the tonsillar lymph glands are similar in the two groups. Moreover, complete enucleation of the tonsils before there were any signs or symptoms of rheumatism (on an average two years before) did not prevent its onset or diminish its frequency. Nor did it in any way lessen the incidence of rheumatic carditis. Thus there is no evidence to support routine tonsillectomy at an early age as an attempt to prevent rheumatism. Incomplete enucleation of the tonsils is followed by an increased tendency to develop rheumatism. The only justification for their removal in a rheumatic child is when the general health is being undermined by repeated sore-throats or very septic tonsils. Especially is their removal contra-indicated during or immediately after an attack of rheumatism.

We should like to thank Dr. H. C. Cameron, in whose out-patient department some of these children attended at Guy's Hospital, and the medical superintendent of Queen Mary's Hospital, Carshalton, for the notes about other patients during their residence there. One of us (E. C. W.) would like to acknowledge a grant from the British Medical Association which helped in this work.

INFECTIOUS PUERPERAL FEVER.

BY A. LEYLAND ROBINSON, M.D. LOND.,
F.R.C.S. ENG.,

LECTURER IN OBSTETRICS AND GYNÆCOLOGY, UNIVERSITY OF LIVERPOOL; HON. SURGEON, HOSPITAL FOR WOMEN, LIVERPOOL;

AND

GERTRUDE E. CUTTLE, L.M.S.S.A. LOND.,
D.P.H. LIVERP.,

SENIOR MEDICAL OFFICER, SMITHDOWN ROAD INFIRMARY, LIVERPOOL.

ALTHOUGH it is admitted that puerperal fever may arise from a pre-existing focus in the genital tract, such as the glands of the cervix, examples of auto-infection are considered to be rare, and for a long time it has been customary to teach that the inflammatory sequelæ of labour are due to direct inoculation of some part of the birth canal from without. As a result of these modern views, which the general public has been quick to absorb, there is a widespread impression that puerperal fever is usually set up by direct contact, and is therefore the result of faulty technique or lack of skill on the part of the midwife or doctor.

Whilst no modern surgeon will question the necessity for a careful technique in the conduct of labour, there can be no doubt that the importance of such technical details has been greatly exaggerated; indeed, the employment of an elaborate ritual is in itself open to criticism, for it is obviously absurd to regard the natural act of labour as a surgical emergency. Striking proof of this assertion is afforded by the figures produced at the Congress on Puerperal Sepsis held in London in 1925, where it was shown that of all the fatal cases of puerperal sepsis presented to the meeting approximately 30 per cent. had occurred after perfectly normal labours, and the bulk of fatalities was not derived from patients who had received serious shock and trauma during labour. On the contrary, it is a by no means uncommon experience to find that many patients who receive a great deal of trauma during delivery make uninterrupted and afebrile recoveries, and it has long been known that the incidence of puerperal fever is not necessarily increased by the presence of infective vaginal discharges during pregnancy. These anomalies are partly explained by the variations in virulence of the causal organisms, and partly by the different degrees of immunity that are found in individual patients, but these variants are not a complete explanation of the astonishing but well-established fact that severe and sometimes fatal puerperal sepsis may follow a perfectly normal labour conducted in the presence of the most modern surgical surroundings.

It is, of course, universally acknowledged that birth injuries and faulty technique are both dangerous allies of puerperal infection but, if septicæmia may and actually does develop without their assistance, it is clear that other factors must be taken into account in order to explain the origin of the fever. Amongst these factors are two which have received little attention, namely:

1. The invasion of the body through extragenital portals such as the throat.
2. The occurrence of indirect modes of infection as opposed to direct contagion in the spread of the disease.

In order to illustrate how by these means puerperal sepsis may assume an epidemic form, we wish to bring forward a group of cases lately under our care, in which the birth canal was not the portal of entry, and the organisms were not conveyed by the hands or instruments of the obstetrician.

Case 1. July 28th.—A young primipara, three weeks after a normal labour and an afebrile puerperium, developed a sore-throat, fever, and a typical scarlet rash, and was transferred to the fever hospital.

Case 2. August 1st.—A multipara who had been delivered normally the previous day complained of a sore-throat and some backache, and was found to have a temperature of 100° F. The next day there was pain in the breast and later a breast abscess was opened and drained. The baby developed in the right eye an ophthalmia, bacteriologically negative to gonococci.

Case 3. August 1st.—A multipara on the seventh day of the puerperium developed a temperature of 101° F. which persisted for some days without other symptoms, except increase of the pulse-rate.

Case 4. August 1st.—A multipara who had been delivered of twins nine days previously was found to have a temperature of 102·8° F. and a rapid pulse. Glycerin injections of the uterus were started, and she was given anti-scarlet fever serum and radiostoleum capsules. Throat swabs were negative, but she had the clinical appearance of septicæmia, and for some considerable time was dangerously ill. She eventually recovered. Both babies developed fever and scarlet rashes; both recovered.

Case 5. August 5th.—A two-para was delivered of living twins on August 3rd, the labour being perfectly natural in every way. On the 5th the temperature rose to 103·4° F. and the pulse-rate to 134. Glycerin injections and anti-scarlet fever serum were given, but the patient died on August 9th, six days after delivery. The post-mortem showed the usual signs of septicæmia. Both babies developed scarlet fever, and one died two days after the mother. The second was transferred to the fever hospital.

Case 6. August 6th.—A multipara delivered on the 1st inst. complained of general malaise and some tenderness in the right breast. The temperature rose to 101° F. and the tongue was slightly suspicious of scarlet fever. She was given anti-scarlet fever serum, and gradually recovered without any local infection of the breast. The child ran a temperature between 99° and 100° for ten days, and showed an atypical scarlet rash on both legs.

Case 7. August 10th.—A baby born on the 5th was found to have a temperature of 102° F. A scarlet rash appeared two days later; the mother remained afebrile.

Case 8. August 12th.—A multipara delivered six days previously complained of acute pain in the groin with fever; later the right breast was inflamed and she developed an abscess. The baby ran a temperature for some days without any other symptoms. Both made a good recovery.

Case 9. August 23rd.—A baby four days old developed a rash on its chest and a temperature of 102·4° F.; the rash was suggestive of scarlet fever. The mother also ran a slight temperature, and had a painful nodule in one breast.

Case 10. August 24th.—A multipara developed a temperature of 104° F., with quickening of the pulse-rate. She had been delivered normally three days previously and was subject to rheumatism. The pyrexia persisted for some days, but there were no other physical signs. The baby, however, developed a scarlet type of rash which was accompanied by a slight rise of temperature.

Ophthalmia.—Between July 30th and August 9th five cases of ophthalmia were reported in the wards. The swabs of all were negative to gonococci; three of the cases were unilateral and two bilateral.

These cases of puerperal sepsis constitute a small epidemic of scarlet fever, for although the clinical manifestations were neither uniform nor typical, but included breast infection and ophthalmia, we have no doubt that the whole series was due to the same organism and derived from the initial case of scarlet fever. Fortunately the latter was typical and easily recognisable, for if the nature of the illness of this patient had been overlooked (and ambulant cases of scarlet fever may easily escape notice), then the whole significance of the epidemic would have been missed; the fever would have been attributed to the ordinary channels of infection, and this would have led to a careful but futile revision of the technique in use in the hospital. Such an inquiry was, indeed, carried out in the present instance, but it threw no light on the origin of the outbreak; no fault could be found in the methods or the personnel, whose efficiency is established by the morbidity-rate of the hospital, which is definitely below the average. In our opinion the septic manifestations in these women and babies were the result of invasion by an air-borne organism, and not due to primary involvement of the genital tract through direct contact. We do not wish to tonsillectomy, chorea is more likely to be met with than if tonsillectomy had not been performed. In view of the possible relations of diseased tonsils to rheumatic heart disease we are summarising this investigation with reference to tonsillar sepsis in non-rheumatic children, and in rheumatic children without cardiac involvement, with temporary cardiac involvement, and with permanent cardiac involvement (Table XVII.). There is no evidence that there is any relationship between tonsillar sepsis and the development of temporary or permanent carditis. It is important to see whether complete tonsillectomy before the onset of rheumatism causes the heart to be spared when rheumatism develops. The results are shown in Table XVIII., and there is no evidence at all that the heart is spared. Contrary to the suggestion of Reginald Miller,[1] tonsillectomy is no more use as a prophylactic against the heart becoming involved in cases of rheumatic fever than in cases of chorea. Actually in our series the highest percentage developing carditis was among the choreic children whose tonsils had been removed earlier.

SUMMARY AND CONCLUSIONS.

Rheumatism occurs so frequently in the children of the poor that 15 per cent. of these above the age of 3 attending two hospitals in South-East London attend for this disease. Our impression is that the poorest are the most commonly affected, and it is certainly as common in them as in children of the artisan class. This is contrary to the findings of the Reports of the Medical Research Council and the British Medical Association.[1] [2]

Among these 250 cases three girls are affected for every two boys, and this sex preponderance is more marked in chorea. Rheumatism rarely occurs before the age of 4, and chorea rather later. The commonest age for the onset is 6 or 7 years, after which there is a slight decline. But later chorea forms a larger proportion, probably owing to the strain of life at school.

A family history of rheumatism occurred in nearly 60 per cent. of these cases, but in only just over 20 per cent. of some non-rheumatic controls; it is therefore an important ætiological factor. Further, it has an influence in determining which rheumatic manifestation is likely to occur, for chorea was found more often where there was a family history of chorea.

An attack of rheumatism is more likely to start during the winter months from November to April.

One of the most important factors predisposing to rheumatism is a debility. Thus an attack often follows the specific fevers—e.g., measles or scarlet fever. "Cyclical vomiting" is of little importance in this respect.

In the same way tonsillitis may predispose to rheumatism. In almost every case in this series, where there was a history of related tonsillitis, there was a latent period of from several days to three to four weeks. If the infecting organism gains an entrance during the attack of tonsillitis this is contrary to the idea that it is a streptococcus. Children who have once had rheumatism should be kept indoors for at least two weeks after tonsillitis.

A systolic murmur was heard during the height of the illness in about half these patients, and was much less common in chorea than in other cases of rheumatism. Permanent signs of heart disease remained in 15 per cent. of the "out-patients" and in 30 per cent. of those who had been treated as in-patients at Carshalton, obviously because these had suffered from much more severe attacks of rheumatism or chorea. In spite of this there were only about half the number of relapses among those patients who had been given a long course of institutional treatment at Carshalton.

There is no evidence that the tonsils of rheumatic children are more septic than those of non-rheumatic children attending as out-patients. The frequency of tonsillitis, the septic appearance of the tonsils, and the degree of enlargement of the tonsillar lymph glands are similar in the two groups. Moreover, complete enucleation of the tonsils before there were any signs or symptoms of rheumatism (on an average two years before) did not prevent its onset or diminish its frequency. Nor did it in any way lessen the incidence of rheumatic carditis. Thus there is no evidence to support routine tonsillectomy at an early age as an attempt to prevent rheumatism. Incomplete enucleation of the tonsils is followed by an increased tendency to develop rheumatism. The only justification for their removal in a rheumatic child is when the general health is being undermined by repeated sore-throats or very septic tonsils. Especially is their removal contra-indicated during or immediately after an attack of rheumatism.

We should like to thank Dr. H. C. Cameron, in whose out-patient department some of these children attended at Guy's Hospital, and the medical superintendent of Queen Mary's Hospital, Carshalton, for the notes about other patients during their residence there. One of us (E. C. W.) would like to acknowledge a grant from the British Medical Association which helped in this work.

occurs at a distance from the actual site of injection. With quinine, on the other hand, there is a distinct tendency for the inflammatory process to spread widely beyond the point of injection. In several of our cases this spread was very extensive, a single injection in the calf resulting in an intense reaction affecting the whole length of the saphenous vein *right up to the saphenous opening.* Failure to produce any reaction at all was more common with the weaker (20 per cent.) sodium salicylate solution.

Everyone agrees that the pain produced by sodium salicylate, especially the stronger solutions, is a serious disadvantage. It is true that a local anæsthetic such as ethocaine may be added, but this involves a risk of unrecognised extravasation, as emphasised by Sicard.

Quinine and urethane injections are not open to this objection, but the after-aching may be considerable, and in a few of our cases intense and cramp-like pains have followed use of this solution; in one or two instances these have persisted for several weeks. Lastly, the duration of treatment in cases with extensive varicose veins often proves long and wearisome.

It seems to us therefore desirable to find some substance which will more completely satisfy the ideal requirements. We suggest that sodium morrhuate will do so. This substance has been employed as an intravenous injection for other therapeutic purposes, and one of us (P. B. K.) had noted its effect on the vein injected and suggested its possibilities for our present purpose. Accordingly it was tried and proved satisfactory. By careful observation and experiment over a prolonged period we have arrived at what we consider to be the most advantageous method of using it.

Sodium morrhuate is the sodium salt of a fatty acid extracted from cod-liver oil. In solution it is dark brown in colour, soapy in consistency, and has the characteristic cod-liver oil smell. It has been prepared for us by the British Drug Houses, Ltd., in ampoules containing 5 c.cm. of the sterilised solution. A small quantity of carbolic acid (to 0·5 per cent.) is added as a preservative, though this is not absolutely necessary. We would emphasise the fact that the carbolic has nothing to do with the reaction produced on injection, as the pure solution gives the same results. The two strengths prepared for us are 5 per cent. and 10 per cent. In cold weather the solution will frequently appear partially coagulated. The phial should then be immersed for a few minutes in warm water, when the contents will clarify except for a slight permanent haze. It is not necessary to inject the solution hot. In loading the syringe it is advisable to employ a large-bore needle, as the solution rather easily becomes frothy. This is changed for the fine needle before making the actual injection.

Effects of Injection.

1. *General.*—Sodium morrhuate has no toxicity, and amounts up to 10 or 12 c.cm. of the 10 per cent. solution have been given at one time. No general symptoms have occurred in any of our cases. The solution lakes the blood as does sodium salicylate, but this effect seems of no practical consequence.

2. *Local.*—The effect on the injected vein is usually prompt and striking. The vein at the site of injection becomes swollen and hard within a few moments for a distance up to an inch. On withdrawal of the needle the puncture seals itself quickly and subsequent extravasation does not occur. This fact enables a succession of punctures to be made rapidly with safety. In certain cases the vessel wall contracts, and swelling and hardening do not appear; though this usually augurs failure, obliteration of the vein lumen not infrequently follows. An important point is that sodium morrhuate is for practical purposes innocuous to the subcutaneous tissues. One of us (P. B. K.) has injected quantities up to ½ c.cm. into his own arm without any ill-effect beyond a slight local tenderness. The reaction on the vein produces very little discomfort. There is usually an aching sensation and a feeling of stiffness, which may persist for 24–48 hours, but it is seldom at all severe.

3. *Subsequent Course.*—The treated vein passes through the stages well recognised in the case of other irritants. The firm solid swelling persists, and we would emphasise the fact that the total effect is usually seen immediately after the injection is made. During the succeeding days the reaction shows little or no tendency to spread, either along the course of the vein or through its wall. In other words, obliteration of the lumen is ensured with a minimum of inflammatory reaction.

Details of Technique.

Dosage.—The 5 per cent. solution is usually quite strong enough. We only use the 10 per cent. strength when the weaker solution has failed or has produced a thickening of the vein wall without obliteration of the lumen. In most cases ½ to 1 c.cm. is the correct dose for each injection, the exact amount being determined by the size of the vein. The reaction produced is in direct proportion to the quantity of the solution injected. Over-dosage will lead to excessive local reaction, and some of our earlier cases developed a periphlebitis from this cause. With correct dosage and spacing of punctures we are confident that periphlebitis should be rare.

Total Dosage.—We have found it perfectly safe to go up to 10 c.cm. at one sitting, and indeed we have exceeded this. In practice such large quantities are not often required; in most cases all affected veins can be dealt with at one sitting without the use of anything like this total quantity. Some nervous patients are unable to tolerate many punctures at one time, and this may limit the extent of vein which can be treated at a sitting.

Method of Injection.—Sodium morrhuate appears to give its best reaction in a distended vein. Therefore the injections are made with the patient standing, except where the veins are so large as to remain full when he is sitting or lying down. Each puncture is made with the usual precautions, using a fine needle and an all-glass syringe. Each dose is injected rapidly; the needle is withdrawn and the skin is momentarily compressed while the next puncture is being made. Oozing ceases automatically as the vein swells. Successive injections are made rapidly, usually from above downwards, the sites selected being spaced out so that an inch and a half to two inches of vein intervenes between each. The patient lies down for a few moments after the injections. The puncture wounds may be touched with collodion, but usually no application at all is needed and we dispense with all bandages or other forms of compression.

If a further treatment is necessary it is arranged after a week's interval. If all the injections considered necessary have been completed, an inspection is made a month later and any further injections which may be considered needful are then given.

Results.

We have used this solution exclusively in treating varicose veins for the past ten months. During that period we have dealt with 187 cases. Among this series there has been no instance of necrosis, and there have been only 13 known instances of periphlebitis. The average number of sittings has been 1·82 per case. In such cases as we have been able to see after an interval of six months has elapsed the results have been satisfactory.

Conclusions.

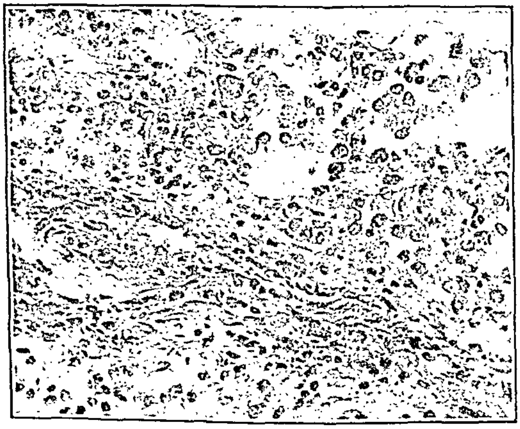
In sponsoring this new addition to the lengthy list of therapeutic agents employed in the treatment of varicose veins we feel justified in claiming for it certain merits. 1. The solution is free from the risk of general toxic effects. 2. The phlebitis induced is effective and controllable, and the risk of local complications is slight. 3. The treatment is as free from pain and discomfort as can be reasonably expected of any artificially induced inflammatory process. 4. The time occupied in treatment is the briefest possible.

THE ASCHOFF NODULE IN RHEUMATIC PNEUMONIA.

BY A. D. FRASER, M.B., CH.B. GLASG.,
PATHOLOGIST, BRISTOL ROYAL INFIRMARY.

IT has long been known that the lungs may be affected during the course of acute rheumatic fever, and much has been written on the subject from the clinical point of view. The pathogenesis of the lung condition has, until lately, been unknown, chiefly owing to lack of material for investigation, since few subjects of this disease die during the acute stage. The clinician has generally regarded the lung signs and symptoms in acute rheumatic fever as a sequel to cardiac insufficiency, pleural effusion, paralysis of the diaphragm, or to pressure on the lung from an enlarged heart or pericardial exudate. The frequent implication of the base of the left lung has lent support to some of those theories. Rabinowitz, however, in 1926[1] studied a series of patients in the acute phases of rheumatic fever, paying particular attention to the pulmonary signs and symptoms. He found that there was a group with pulmonary manifestations which could not be explained as secondary to cardiac insufficiency or pressure. These cases showed irregular elevation of temperature, areas of marked dullness in the chest, and loud bronchial breathing. Upper respiratory symptoms were slight. These signs were of a fleeting character, disappearing in one area to reappear soon in another, and as a rule did not influence the prognosis. Rabinowitz did not have much opportunity for histological examination, but believed that the condition must be a specific pneumonia due to the virus of acute rheumatic fever. We now know that a particular type of pneumonia is the cause of those chest signs. Naish[2] was the first to describe some of the histological features of this pneumonia and to emphasise its specific nature. He did not find the Aschoff nodule in the lungs of his cases. The purpose of this paper is to bring forward further proof that such a pneumonia does occur, and that it is of a specific type, since it bears the signature of the acute rheumatic fever virus—the Aschoff nodule.

FIG. 1.



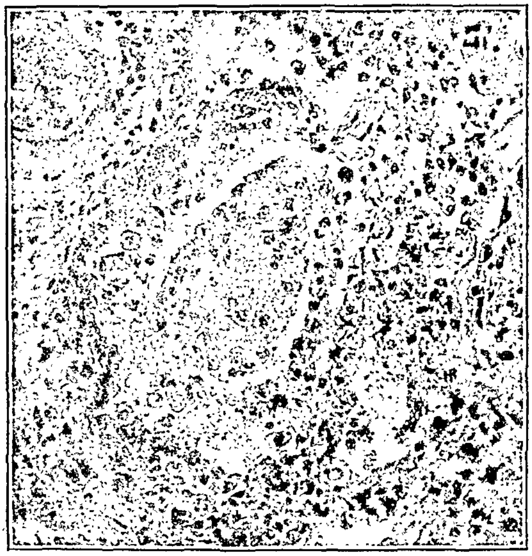
Proliferation of pleural endothelial cells with cellular infiltration and fibrosis of the subpleural tissue.

During the course of a pathological investigation into rheumatic fever patients, dying apparently in the acute stage, pulmonary lesions were found in two.

Clinical History and Autopsy Findings.

CASE 1.—A. B., female, aged 20. Admitted to hospital in an acutely ill condition with swollen painful joints and pain in the chest. History of an attack of acute rheumatic fever two years before. Temperature 102·4° F. on admission, then varying each day from 98·6° F. in the morning to 101° F. in the evening. Pulse-rate remained almost constant at 120. Respiration varied between 40 and 48. There was dullness and bronchial breathing at the back on both sides of the chest well up to the apex. A diagnosis of pneumonia was made. Death took place on the eleventh day after admission. Some days before death about 120 c.cm. of blood-stained fluid was withdrawn from the pericardial sac. A fibrin clot formed in this fluid soon after. The cell count was polymorphs, 72 per cent.; lymphocytes, 21 per cent.; endothelials, 7 per cent.

FIG. 2.



An alveolus full of alveolar cells. The cells at the periphery are degenerated.

Post-mortem examination revealed a typical acute rheumatic pericarditis and endocarditis of the mitral and aortic valves. The heart was enlarged, and on microscopic examination of the myocardium many Aschoff nodules were found. There was a little blood-stained fluid in each pleural sac. Both lungs were markedly congested and heavy, also the lower lobes had a rather solid feel. There were small groups of subpleural punctate hæmorrhages scattered here and there over both lungs. On the pleural surface of both lower lobes there was a thin, somewhat rugose, fibrinous exudate. The consistency of these lobes was like solid indiarubber. The cut surface exuded blood, and was smooth in appearance. The general colour was a purplish red, but here and there a few greyish areas were seen. The surface was not uniformly solid in appearance, owing to the presence of aerated portions in places. Small pieces cut from the solid areas just floated when placed in water. The liver and kidneys showed marked parenchymatous degeneration, and the spleen was double the normal size. The cut surface of the spleen showed acute congestion, but there was no softening of the pulp. Cultures made from the surface of the freshly cut lung were sterile.

CASE 2.—C. D., male, aged 15. Admitted with a diagnosis of meningitis. Died two hours after admission. No history of previous illness, except that the patient was subject to curious fit-like attacks when in bed at night. These attacks lasted about ten minutes, and had been going on for 15 months.

Post-mortem examination.—Thrombosis of the internal jugular vein, right lateral, and longitudinal sinus, and most of the cerebral veins on the right side with a few on the left. No evidence of ear or sinus infection. The heart showed hypertrophy, and there was typical acute rheumatic endocarditis of the mitral and aortic valves. There was no evidence of old or recent pericarditis. A microscopical examination of the myocardium revealed patchy fibrosis, but no Aschoff nodules. The medium-sized coronary arteries, however, showed endarteritis. This endarteritis was of the type found occasionally in the coronaries of old-standing rheumatic fever cases. There was chronic venous congestion of the lungs, and the pleura over both lower lobes was much thickened. Section of the left lung revealed in the cardiophrenic angle a moderately large solid area. The surface was pale and smooth, with fibrous areas here and there, and an occasional cystic bronchial space. Cultures made from the freshly cut surface of this solid part of the lung were sterile.

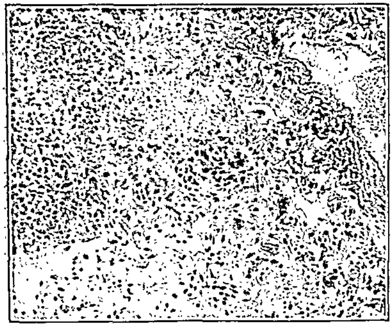
FIG. 3.



An Aschoff nodule in an interlobular septum.

Pathological History of the Lungs.

A microscopical examination of the lungs from Case 1 revealed a characteristic form of pneumonia and pleurisy which has not yet been completely described by any observer. The pneumonic lesion was rather patchy in its distribution with some tendency to be confined to lobules. Between these patches the lung tissue presented the appearance of chronic venous congestion. In one respect there was a slight resemblance to what is seen in ordinary broncho-pneumonia, for at the peripheral zone of the pneumonic areas the alveoli contained serous exudate and a few cast-off alveolar cells.

Since all stages of the morbid process may be present in any chosen area it facilitates matters to describe the changes as they were seen in the different lung structures.

Pleura (Fig. 1).—There was marked proliferation of the pleural cells, which were found in several layers and in small heaps entangled in a thick fibrinous exudate. Many of these cells were large and multinucleated. In places the more or less normal pleural endothelium was being raised by a fibrinous exudate underneath, and in other parts this exudate lay on the surface and endothelial cells were absent. The subpleural layer was undergoing fibrotic transformation, and all the vessels showed marked endothelial proliferation, even to complete blocking of the lumen. In and around the walls of these vessels there were collections of cells of varying type, but an endothelial cell with vesicular nucleus predominated. The others were lymphocytes, plasma cells, or connective tissue cells. Polymorph leucocytes were not seen in any great number. These vessel changes were found not only in the subpleural layer but everywhere throughout the lung, and will be described more fully further on.

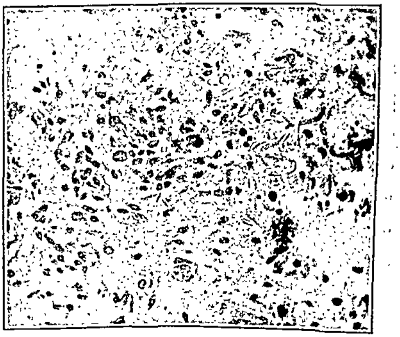
Alveoli (Fig. 2).—The proliferation of the alveolar lining cells was the most prominent feature; many of these cells were multinucleated. Cells containing pigment granules were scanty. Usually a few polymorphs or lymphocytes were present in the alveolus in addition to the others. The later change in these alveolar cells was rather striking. They became necrotic and their fused necrotic protoplasm formed a ribbon-like lining to the inner surface of the alveolus. The centre of the alveolus contained a few mononuclear or polymorphonuclear cells and sometimes serous exudate. In many places this ribbon-like mass was found lining larger cavities which had arisen by fusion of two or three alveoli through disappearance of the intervening alveolar walls. Occasionally areas were found containing nothing but polymorph leucocytes, with the remains of alveolar septa scattered here and there.

Bronchi.—The bronchial wall was infiltrated with small round cells, endothelial cells, and fibroblasts. At later stages the muscle and fibrous layers became disintegrated, and there was some proliferation of the mucosa cells so that they formed two or three layers. The final stage of this process was either complete disappearance of the entire wall and mucosa or the formation of a cyst-like cavity lined by the remains of the bronchial wall. The presence of an occasional globular-like body in areas where there were no traces of bronchial structure was rather puzzling, until they were traced out as the globular remains of a bronchial cell. The bronchi lying outside the affected parts of the lung were unchanged.

Connective Tissue.—The changes here were chiefly of a proliferative and exudative character, associated with the appearance of endothelial-like cells and necrosis of the collagen fibrils. These endothelial cells varied in size—some being very large and multinucleated. As many as nine nuclei were seen in one cell. The cytoplasm of these cells tended to be basophilic and the nuclei were vesicular. They were most conspicuous in the fibrous septa of the lung. Sometimes there were rows of such cells forming a palisade arrangement along the septa. In places they were grouped as rounded nodules, and at times the outpouring of a serous exudate into the interstitial tissue had scattered the cells far and wide. Occasionally fibroblasts were seen, particularly in those parts of the septa where the endothelial cells were scanty. *The nodules were made up of these endothelial* cells with here and there, generally at the periphery, a few lymphocytes or plasma cells. Neutrophil polymorphs were as a rule scanty and eosinophils were absent. Very rarely a nodule was seen composed of two or three endothelial cells surrounded by polymorphs only. Usually the centre of the nodule was occupied by granular material suggesting necrotic endothelial cells, and occasionally streaks of fibrin were seen lying between the cells. The nodules, as a rule, were found in close association with the smaller vessels, and in some cases the nodule cells were penetrating and destroying the vessel wall. Always these vessels showed endothelial proliferation, sometimes so marked as to completely close the lumen. Occasionally the vascular endothelium was raised from its base by serous exudate.

On comparing the vascular changes with those in the subpleural layer it was seen that the morbid process was essentially the same, but that in the latter case the endothelial cells were not so numerous and did not form the typical aggregations.

FIG. 4.



High-power view of nodule shown in Fig. 3.

The nodules here described (Figs. 3 and 4) were exactly similar in structure, cell content, and situation to the Aschoff nodules found in the myocardium in acute rheumatic fever. No micro-organisms were demonstrated in the sections from the lungs. The microscopical appearances of the lung from Case 2 suggested a chronic stage of the lesion just described. The solid area in the cardiophrenic angle was composed of fibrous tissue, compressed alveoli with cubical epithelium, and areas of alveoli full of proliferated alveolar cells with remnants of mucosa from the smaller bronchi scattered here and there. The remaining bronchi were cystic and numerous cells were present in the walls, which were partially disintegrated. These cells were lymphocytes, plasma cells, and fibroblasts. Polymorph leucocytes were usually absent. The bronchial mucosa either formed a thick lining layer—often four cells deep—or the space was completely filled with mucosal cells. All of the vessels showed advanced endarteritis—often a solid cord only being left. In regions of the lung widely separated from the solid portion somewhat similar changes, but to a lessened degree, were observed. These changes consisted in cellular infiltration of the bronchial wall and some proliferation of the mucosal cells. There was also perivascular fibrosis and endarteritis. Here and there small groups of alveoli were filled with alveolar cells. No Aschoff nodules were observed in any of the areas. In suitably stained sections no micro-organisms were detected.

Conclusion and Summary.

From a histological study of the lungs from two cases of acute rheumatic fever it has been shown that there is a specific form of pneumonia which occurs during the course of acute rheumatic fever. This pneumonia may be accompanied by pleurisy. The lung lesion in its acute stage is a severe one and is characterised by vascular changes, proliferation, then necrosis, of alveolar cells, and destruction of the bronchi in the areas involved. It resembles in its general features an acute interstitial pneumonia. Typical Aschoff nodules are found in the interstitial tissue of the lung and are most prominent in the interlobular septa. These Aschoff nodules are usually found in close association with the smaller vessels. The condition may pass into a chronic or quiescent stage characterised by varying degrees of endarteritis, destruction of lung tissue, and fibrosis. In the chronic stage the Aschoff nodule is apparently absent.

I am indebted to my colleagues on the staff of the Bristol Royal Infirmary for the clinical histories of the cases.

ELEPHANTIASIS TREATED BY PROTEIN SHOCK.

BY G. CARMICHAEL LOW, M.D. EDIN.,
F.R.C.P. LOND.,
SENIOR PHYSICIAN, HOSPITAL FOR TROPICAL DISEASES, LONDON, AND SEAMEN'S HOSPITAL, ROYAL ALBERT DOCKS; CONSULTING PHYSICIAN FOR TROPICAL DISEASES, TILBURY HOSPITAL;
AND
D. STRANGWAYS DIXON, M.R.C.S. ENG.,
HOUSE PHYSICIAN, HOSPITAL FOR TROPICAL DISEASES.
(From the Hospital for Tropical Diseases).

IN THE LANCET of Feb. 25th, 1928, Dr. W. E. Cooke, medical superintendent of the Hospital for Tropical Diseases, published a note on a case of early elephantiasis which we treated with protein shock.

The patient, a young woman of 26, was born and had lived most of her life in Madras. On a voyage home to England in 1927 her right leg became red, painful, and swollen, so when she arrived in London she came into the Hospital for Tropical Diseases. An examination there showed that the right leg was swollen below the knee, the œdema being of the solid type, and the glands in both groins were swollen, palpable, and tender. Apart from slightly enlarged tonsils on both sides nothing else abnormal was found. There was, however, an eosinophilia of 10 per cent.; the case was diagnosed as early filarial elephantiasis.

The treatment, T.A.B. injections intravenously, was given in February, 1927, and she left hospital on March 25th of the same year. After this she had a tonsillectomy performed. In May th[illegible] was quite satisfactory, with no signs of swelling, and in a letter Dr. Cooke received from her in August, 1927, she stated that she had been working hard and taking plenty of exercise but that there was still no sign of swelling in the leg. A further report written on Nov. 20th, 1927, from India, stated that she was travelling constantly as her work demanded and that, though she was not resting especially, the limb had shown no signs of swelling and measured the same as the other leg. We have not heard further since that date, so are unable to say whether the result is permanent.

As the result in this case has been promising, I have gone on trying protein therapy and have recently given it in a small series of similar cases. The following are the details.

CASE 1.—A married man of 60, with two children, complained of swelling of the right leg. He had been born in London and had once been in Paris 40 years ago, but otherwise never out of England. His family history was good and his use of alcohol and tobacco moderate. He had had measles, chicken-pox, mumps, scarlet fever, and two attacks of influenza, as well as having suffered from asthma for many years. In 1921 he fell off a bicycle and fractured his right clavicle.

In October, 1927, the right leg below the knee, for no apparent reason, became swollen. A doctor gave electrical massage for this, with the result that the leg quickly returned to normal. In June, 1928, there was another attack, the leg swelling up again and the temperature rising, and this time the thigh became involved as well. Massage was given but a certain amount of swelling remained below the knee when the acute attack had subsided. In October, 1928, another febrile attack occurred and the whole of the right leg became greatly swollen again. A series of six injections of collosol manganese, at weekly intervals, was given, but produced no appreciable result. In 1929 there were two further attacks, the last one being at the end of May. The patient was admitted to the Hospital for Tropical Diseases on June 6th, 1929. He looked thin but not emaciated. His teeth were fair; he had a plate in the upper jaw. The tonsil on the right side was enlarged and septic. The heart was normal and there were no signs of asthma in the lungs. Nothing abnormal was palpable in the abdomen, but the veins were prominent, especially over the right side. There was no enlargement of the liver or spleen. The right leg was much swollen both above and below the knee. There was no redness, but solid œdema—typical elephantiasis. The left leg was normal. The fæces, urine, and blood gave negative pathological reports and the Wassermann reaction was negative. X ray examination showed a few calcified glands in the left inguinal region. A diagnosis of elephantiasis nostras was made.

The patient was given a series of five T.A.B. inoculations intravenously at five-day intervals, the initial dose being 50 millions, increasing to 200 millions. He left hospital on August 13th, 1929, the leg being slightly better. He was told to report if anything further developed. He kept well until August 21st, when he vomited and had pyrexia, and the leg and glands became swollen and painful again. The attack lasted for two days. On Sept. 11th he had a further attack and was readmitted to hospital. A further T.A.B. inoculation of 200 millions was given. He left hospital again on Sept. 19th, 1929, and reported later by letter that he was no better.

CASE 2.—A married Indian woman of 37 with two children complained of permanent swelling of the left leg. She had been born and had lived in India all her life until May, 1929, when she came to England. Her father had died of dropsy and her mother had suffered from elephantiasis. She had had measles and dysentery. As a girl she had fallen from a balcony and injured her left ankle, being laid up for a month.

In 1909, when 17, she noticed that her left leg swelled below the knee every evening. A few months later she had an attack of ague and a swelling developed in her left groin. Her temperature was 103° F. and her whole leg became swollen, inflamed, and painful to touch. After three days these symptoms subsided. The attack, however, was followed by similar ones, and eventually a definite elephantoid condition developed. In 1912 she entered a local hospital, where she was treated with local applications and quinine therapy, the attacks subsequently being less frequent. In 1917 she again had severe attacks of lymphangitis and her leg was incised in several places on the supposition that pus was present, but nothing was found. In 1919 there was definite permanent thickening, and by this time the right leg was noticed to be swollen also. For the last ten years the condition has increased, recurrences of the febrile attacks taking place from time to time. The patient was admitted to the Hospital for Tropical Diseases to see if anything could be done for her. Her teeth were good and there was no enlargement of the tonsils or sign of oral sepsis. Her heart and lungs were normal. The liver and spleen were not enlarged and nothing abnormal was palpable. Vaginal and rectal examinations were negative. Both legs showed permanent swelling of the feet, ankles, and up to the knee, the left much more marked than the right—typical elephantiasis. The examination of fæces, urine, blood, and Wassermann reaction was negative, and no microfilariæ were found in the night blood. A diagnosis of filarial elephantiasis was made.

A series of five T.A.B. injections similar to those given in Case 1 was administered, but little reaction followed. She left hospital on August 14th, 1929, and was told to report in due course. She returned in October, reporting another attack of lymphangitis with increased swelling of the legs.

CASE 3.—A bachelor, aged 43, had attacks of pain and swelling across the dorsum of his right foot. He had been born in England and had resided in Sumatra in 1912, Seychelles and Uganda in 1919, and in India, Ceylon, Java, and Malaya in 1921. He had had inflammation of both lungs, measles, erysipelas of the legs, hæmoptysis in 1909, and in 1914 hyperpyrexia supposed to be due to sunstroke.

During 1924, whilst in Travancore, his right foot became swollen, his joints ached, and he had pyrexia. Since that time he had had repeated attacks of swelling in the same place, sometimes as often as every third week. Of the many and various treatments tried, salicylates alone seemed to have been effective in warding off a recurrence. Since his arrival in England in October, 1928, he had kept well except for a little tightness across the dorsum of the right foot. He was admitted to the Hospital for Tropical Diseases on Jan. 11th, 1929. The general examination was negative. No glands were found on deep palpation in his iliac fossæ. There was thickening of the tissues in Scarpa's triangle and over the proximal ends of the metatarsal bones of the right foot. A blood count showed: 5,100,000 red cells; 7200 white cells; hæmoglobin, 90 per cent.; polymorphonuclear leucocytes, 52 per cent.; lymphocytes, 43 per cent.; large mononuclear leucocytes, 2 per cent.; and eosinophils, 3 per cent. No parasites or filariæ were seen. The fæces, urine, and Wassermann reaction *yielded negative results*. X ray examinations failed to reveal calcified filariæ. A diagnosis of "recurrent lymphangitis ? filarial" was made.

The patient was given a series of five T.A.B. inoculations at five-day intervals. No further details are available. The patient promised to report by letter, but so far has not done so.

CASE 4.—A single man, aged 27, complained of swelling of his right leg and ankle. He had been born in Colombo, where he had lived most of the early part of his life. In 1910 he came to England, where he resided until 1925, and then went to India. He returned to England in 1929. He had had measles, chicken-pox, and gonorrhœa in 1927.

In 1927 he had two attacks of fever and pain, associated with swelling of his right leg from the ankle to the knee. He had had, before this first attack, some irritation of the skin of that foot. Both these attacks were diagnosed as lymphangitis. During 1928 there were four similar outbursts, each lasting four or five days. In April, 1929, he was admitted to the Hospital for Tropical Diseases to see if anything could be done for him. He was very stout; his pupils, throat, and tonsils were normal. His heart was a little rapid, but there was nothing wrong with his lungs. The liver and spleen were not enlarged and there were no enlarged lymphatic glands; the knee-jerks were normal. The right leg was swollen at the ankle, but this swelling largely disappeared with rest in bed. A blood count showed: 5,000,000 red cells; 8000 white cells; hæmoglobin, 90 per cent.; polymorphonuclear leucocytes, 61 per cent.; large mononuclear leucocytes, 2 per cent.; lymphocytes, 31 per cent.; eosinophils, 6 per cent. No parasites or embryonic filariæ were found. The urine, fæces, and Wassermann gave negative reactions. The urea content of the urine was 35·25 mg. per 100 c.cm. X ray examination yielded no evidence of calcified filariæ. A diagnosis of filarial lymphangitis was made.

He was given the usual course of intravenous T.A.B. injections; some of these caused severe reactions, his pulse-rate on one occasion rising to 160. He was discharged on May 24th, 1929. He reported on Oct. 23rd, 1929, that so far he had no recurrence of his attacks.

CASE 5.—A single man, aged 53, complained of attacks of swelling in both legs, especially the right. He had been born in England, but had gone to Japan in 1906, where he had been ever since. He had had measles, scarlet fever, and diphtheria; before the age of 16 he had had three epileptiform convulsions.

In 1916 he developed pyrexia with a swelling of his right leg below the knee. This quickly disappeared, but recurrences took place in 1927 and 1928, and in one of these he noticed that his left leg was swollen as well. On admission the right instep and left ankle were the most involved. His teeth were bad, but his tonsils were not enlarged. The left side of the chest was more prominent than the right, but no adventitious sounds were heard and nothing abnormal was found in the heart. His blood pressure was 100/65. The liver and spleen were not enlarged, but the sigmoid colon was just palpable and the groin glands on both sides were enlarged. There was no noticeable swelling of his legs—i.e., no permanent œdema. A blood count showed 4,820,000 red cells; 6000 white cells; hæmoglobin, 85 per cent.; polymorphonuclear leucocytes, 50 per cent.; large mononuclear leucocytes, 2 per cent.; lymphocytes, 47 per cent.; eosinophils, 1 per cent. No parasites, filarial or otherwise, were found. The urine, fæces, and Wassermann reaction were all negative. X ray examination of legs and abdomen gave no signs of calcified filariæ, but in the right leg there was evidence of calcification in the walls of the main arteries, and in the lower two-thirds a faint irregular opacity was seen, indicating scattered calcified deposits. A diagnosis of recurrent lymphangitis of uncertain cause was made.

He received the usual course of T.A.B. injections intravenously, and had good reactions. Reports of further progress are not yet to hand.

Recently F. W. O'Connor[1] has suggested giving injections of sulpharsphenamine locally to see if they would modify the severity and duration of attacks of lymphangitis believed to be filarial and of elephantoid fever. So far he believes they have some effect. It is too soon to speak with any certainty of protein shock by the intravenous T.A.B. injections. In Cases 1 and 2 no apparent benefit resulted; in Case 3 no recurrence has taken place up to date. On the whole, it is doubtful if such treatment will be of permanent benefit, but we have reported the cases in detail to let others try the method on a larger scale in the hope of obtaining some definite proof. Anything that would ameliorate this troublesome malady, even slightly, would be of the greatest value.

EXPERIENCES WITH THE DICK TEST.

HEAT-LABILE AND HEAT-STABLE CONSTITUENTS OF DICK TOXIN.

By

TARO TOYODA, M.D., JOJI MORIWAKI, M.D.,
YASUO FUTAGI, M.B.

(From the Japanese Isolation Hospital, Dairen, Manchuria.)

The Dick Test and Susceptibility to Scarlet Fever.

THE Dick positive rate among 11,284 healthy Japanese in Dairen was 37·2 per cent., which corresponds with the rates obtained by Zingher[1] in New York, and Bókay[2] in Budapest. When the Dick-positive rate and the age-groups of 3000 scarlet fever patients were compared, the highest rate and the greatest number of cases were in the age-period 3 to 5 years; both rates gradually diminished with increasing age. While cases of infection of adults above 16 years of age averaged 4 per 1000, the rate of Dick-positive reactors remained at 13 per cent. The parallelism between the two rates which occurred at the earlier age-periods was no longer observed. We believe that the higher Dick-positive rate above the age of 16 years is due to the appearance in adults of an allergic response to the heat-stable constituent of Dick toxin (vide infra).

Females had a higher Dick-positive rate than males. Of 13,000 healthy Japanese examined, the female Dick-positive rate was 49·8 per cent., the male 34·6 per cent. Males, however, appear to have more opportunities for infection than females, for in spite of the discrepancy in the Dick-positive rates, approximately 50 per cent. of 3000 scarlet fever cases in the Japanese Hospital at Dairen were males. Chinese in Dairen had a much lower Dick-positive rate than Japanese (19·4 per cent. of 3376 tested instead of 37·3 per cent.). During the last six years the morbidity-rate per annum for Chinese has been only 0·08 per 1000; for Japanese 3·61 per 1000. From the returns reported for the last four years 17·7 per cent. of Dick-positive reactors have had a past history of scarlet fever. Two patients under our charge have had a second attack of scarlet fever, and one of these cases ended fatally. It is obvious, therefore, that infection with scarlet fever does not always give absolute immunity.

---

[1] Porto Rico Jour. of Public Health and Trop. Med., 1929, v., 11.

In 305 cases of scarlet fever the result of a previous Dick test was known. Forty-one of these cases (14 per cent.) occurred in Dick-negative and 264 (86 per cent.) in Dick-positive reactors.

There is an interesting relationship between the size and intensity of the Dick reaction and the incidence of scarlet fever in a tested population. During the last four years among 4644 negative reactors the morbidity-rate was 4 per 1000; among 2540 very weak positive reactors 10 per 1000; among 2357 weak positive reactors 29 per 1000; among 1825 moderate positive reactors 54 per 1000; and among 551 strong positive reactors 76 per 1000. The occasional case of scarlet fever amongst the negative or very weak positive reactors cannot be explained away altogether by error in reading the Dick test. That such an error must occur from time to time is obvious when we consider the great variation in rate of development and intensity of positive Dick reactions and the fact that so often patients are only read once.

Ten of 43 Dick-positive reactors who were the hospital attendants of scarlet fever cases developed scarlet fever. On the other hand, there was no case of genuine scarlet fever among 157 Dick-negative hospital contacts. (Twenty-six cases occurred, however, which may be considered as "scarlatina sine eruptione," showing sore-throat as the only symptom.) Seventy-two of 115 primary school-children who had cases of scarlet fever at their homes were positive and six developed scarlet fever. No cases of infection were reported among 63 who were Dick-negative; from these facts a positive Dick test appears to indicate susceptibility to scarlet fever.

Generally speaking, the more intense the Dick reactions the more severe the case and the higher the percentage of complications. Among 14 strong positive reactors there were 29 per cent. of serious cases; among 37 positive reactors 13·5 per cent.; among 22 weak positive reactors 9 per cent.; while among 15 very weak positive or negative reactors no serious cases occurred. There was roughly three times the incidence of complications amongst strong positive reactors as in the Dick-negative group.

During the last four years 76 per cent. of 1380 cases and 13 per cent. of 2164 convalescents have been Dick-positive. In many early cases of the disease a bright rash makes a satisfactory reading of the Dick test impossible. Owing to an early attainment of immunity or, in more severe cases, to a temporary failure of the reacting power of the skin, the Dick positivity in the early stage of scarlet fever is not as high as might be expected. It is also difficult to explain the 6–13 per cent. of convalescents reported in the literature who do not become negative; this may be due to imperfect immunisation or to the appearance of allergy to the heat-stable constituent of the toxin which will be discussed in greater detail subsequently. As a general rule the Dick reaction changes in scarlet fever from positive to negative, but Dr. Kondo,[3] of the Komagome Hospital, Tokyo, has reported the reverse, and this again would apparently be due to the development of an allergic response to the heat-stable toxin. It has been our experience, in common with that of other investigators, that a positive Dick test and inability of the individual's serum to cause Schultz-Charlton blanching indicate susceptibility and a negative Dick test and positive Schultz-Charlton blanching indicate immunity.

Filtrates prepared from the staphylococcus, *Bacillus typhosus*, *B. tuberculosis*, pneumococcus, &c., have been shown to bear no relationship to infection with scarlet fever or its course.

From a consideration therefore of all experiences in Dairen since February, 1925, we are led to the conclusion that the Dick test is a reliable indicator of susceptibility to scarlet fever, the only exception being in those cases in which an allergic response develops to the heat-stable constituent of Dick toxin.

Defects of the Dick Test.

During the last four years we have had 209 cases of scarlet fever among 4733 Dick-positive reactors (44 per 1000) and 48 cases among 7186 Dick-negative reactors (7 per 1000). There is therefore no doubt about the practical value of the Dick test, although when we consider individual cases various questions remain to be answered.

(*a*) Why, when the morbidity from scarlet fever is so low in adults, does the rate of Dick-positive reactors remain above 13 per cent.?

(*b*) Why does the serum of an adult who is a positive reactor sometimes produce a positive Schultz-Charlton reaction?

(*c*) Why have only two of 2700 patients had a second attack of scarlet fever? From 16 to 33 per cent. of children who have had scarlet fever are Dick-positive.

(*d*) Why do some strong positive reactors become negative when a small immunising dose of toxin is given, while certain weak positive reactors, mostly adults, may remain weak positive or may even become stronger positive reactors after repeated immunising injections? When 40,000 S.T.D. are injected into a group of positive reactors, why do say 10–15 per cent. remain positive, although the serum of these positive reactors generally gives a positive Schultz-Charlton reaction?

(*e*) According to various published reports on the Dick test in scarlet fever, 10 to 30 per cent. of patients who are convalescent show a positive Dick reaction. The fact that the serum of many of these produces a positive blanching test cannot be overlooked. Giuffré[4] has observed 2 cases among 12 patients, Abramson[5] 7 among 182 patients, and Kondo[6] 80 cases among 101 patients in which a change in the *Dick reactions was observed during scarlet fever from negative* to positive. The serum of Dr. Kondo's patients produced positive Schultz-Charlton blanching. What has produced the positive Dick reaction?

(*f*) In performing skin neutralisation tests why is it that in some persons complete neutralisation is impossible in spite of an excess of antitoxin in the mixture injected?

(*g*) Why is it that Dick toxin which has been heated two hours at 100° C. is still capable of producing some reaction in certain persons whose serum is Schultz-Charlton positive?

Analyses of Dick Toxin.

The Dick toxin which we have heretofore used for the Dick test and preventive inoculation is a filtrate of scarlet fever streptococcus (Berkefeld W. or Chamberland F. B.) cultured for 4 to 7 days. Recently Ando (1929)[7] has shown that heat-labile and heat-stable constituents are present.

Heat-labile toxin:—To 1 litre of toxin prepared in 0·5 per cent. glucose bouillon, 2 litres of pure alcohol are added, the *mixture being left in the cold room overnight*. The precipitate is then diluted in 100 c.cm. normal saline solution, and the pH is adjusted to 4·0–4·2 by the addition of acetic acid. After 18 hours in the cold room the supernatant is poured off and twice the volume of alcohol added. The process is repeated on four occasions, the precipitate which forms after the operations being the heat-labile toxin.

Heat-stable toxin:—To 1 litre of toxin prepared in 0·5 per cent. glucose bouillon add 5 c.cm. of glacial acetic acid to make the pH 4·0–4·2. Centrifugalise. To the precipitate is added 200 c.cm. normal saline solution and 5 c.cm. N/20 caustic soda solution (the pH should now be about 7·2). The toxin is now one-fifth of its original volume, and may be diluted as required. The process is a difficult one, and the quantity obtained relatively small.

At this stage it is convenient to give the method of preparation of *bacterial endotoxin* (bacterial protein or nucleoprotein) which we think is of a similar nature to the heat-stable toxin.

The streptococcus is cultured for two days in 1 litre of 0·5 per cent. glucose bouillon. The organisms are then washed in normal saline solution, and 100 c.cm. of N/10 caustic soda added. After standing over night in the cold room and centrifugalising acetic acid (5·0 per cent. of 36 per cent. acid to each 100 c.cm. of N/10 soda) is added to the supernatant fluid, making the pH 4·0–4·2. The precipitate which forms is then dissolved in 10 c.cm. of alkaline saline solution.

Heat-labile toxin can be dried; the dry toxin is readily soluble in saline solution. We think that 0·1 c.cm. of 1/500 dilution of the reconstructed dry toxin corresponds to 1 skin test dose (S.T.D.) of the original filtrate. Heat-labile toxin can be inactivated by heating to 80° C. for half an hour. According to Dr. Ando 20 c.cm. will kill a rabbit with diarrhœa, and the toxin, injected intradermally, will cause a positive skin reaction in white pigs. In human subjects it is a true indicator of susceptibility and produces no allergic pseudo-reactions. When used for prophylactic inoculation it may produce in large doses the "scarlatinoid syndrome." The heat-labile toxin is readily neutralised by streptococcus antitoxin but not by anti-nucleoprotein serum.

Heat-stable toxin and streptococcus endotoxin are apparently qualitatively identical. The toxin is not destroyed by heating to 100° for half an hour. It is non-toxic for animals. According to our experiments 0·1 c.cm. of 1/800 dilution of the original endotoxin (concentrated to 10 times) is equivalent to 1 S.T.D. It is this toxin which gives rise to the allergic reactions which we have discussed earlier in this paper. If rabbits are immunised with streptococcus endotoxin, heat-stable toxin and streptococcus endotoxin may both cause flocculation at the same titre. The heat-stable toxin is therefore inferred to be the endotoxin.

Skin Reactions with Heat-labile and Heat-stable Toxins.

1241 subjects were injected in parallel with Dick toxin, heat-stable toxin, and heat-labile toxin and the results were as shown in the following table:—

Skin Reaction to Heat-stable, Heat-labile Toxins, and Dick Toxin (Streptococcus Culture Filtrate) on 1241 Persons.

Group.	Skin reaction to—			Degree of immunity.	Primary school-children.		152 actively immunised school-children.	205 persons with past history of scarlet fever.	190 Chinese coolies.
	Dick toxin (strept. culture filtrate).	Heat-stable toxin.	Heat-labile toxin.		330 of first year grade.	360 of second to sixth year grades.			
					%	%	%	%	%
1	+	−	+	−	39·4	23·3	0	3·4	8·2
2	+	+	+	±	9·4	5·0	0·7	8·8	5·7
3	+	+	−	+	11·2	11·7	13·2	13·2	12·9
4	−	+	−	+ +	17·6	21·1	44·8	29·3	14·9
5	−	−	−	+ + +	17·0	28·1	40·0	38·0	50·5
6	+	−	−		5·5	10·8	1·3	7·3	7·7

(Group 3 = Allergic reaction.)

The immunity of each group would appear to be as follows:—

Group 1. No immunity.
" 2. An intermediate type, showing the development of an imperfect immunity.
" 3 and 4. Immunity (in presence of allergy).
" 5. High immunity (without any allergy).

The sections of the table showing the results obtained with the heat-labile toxin are of special interest.

A study of these results has made us feel that many of the difficulties and discrepancies which all workers with the Dick test have experienced can be explained. If the heat-labile toxin is used for the Dick test the defects of the ordinary Dick test, which can be attributed to the heat-stable toxin contained in the Dick toxin, disappear to a great extent.

Immunisation with Heat-labile and Heat-stable Toxins.

Ten persons who were positive reactors to the heat-labile toxin were given five immunising injections of heat-labile toxin. Ten days after the last inoculation all were negative to skin tests performed with heat-labile, heat-stable, and ordinary Dick toxins. Thirteen subjects who were negative reactors received a similar course of inoculations and remained negative to the triple toxin test.

Fourteen persons who were positive reactors to heat-stable toxin were given five immunising injections of heat-labile toxin. Ten days after the last inoculation only 7 per cent. had become negative; 93 per cent. remained positive to the heat-stable toxin. The 7 per cent. of negatives may be due to the presence of traces of heat-stable toxin in the heat-labile toxin which was used for immunisation. Nine negative reactors received a similar course of inoculations with heat-labile toxin; 56 per cent. became positive to heat-stable toxin. This is difficult to explain except on the assumption that the trace of heat-stable toxin left in the heat-labile toxin which was used for five immunising injections produced allergy in the majority of cases.

Sixteen persons positive to Dick filtrate toxin received immunising injections of heat-labile toxin; 87 per cent. became negative; 13 per cent., like the 7 per cent. in the previous group, showed an allergic response. Seven persons originally negative to Dick filtrate toxin remained negative to the triple toxin test.

Immunisation with heat-stable toxin produced no immunity in most cases. In 21 per cent. of 14 cases positive to heat-labile toxin a negative response was given on re-test with heat-labile toxin. This may have been due to the presence of traces of heat-labile toxin in the heat-stable nucleoprotein used for immunisation. Six negative reactors remained negative on the completion of the injections. Four subjects positive to heat-stable toxin remained positive, and 31 per cent. of 16 subjects negative to heat-stable toxin became positive, an interesting result indicating the development of allergy to the heat-stable constituent. Fourteen persons positive to Dick filtrate toxin showed 58 per cent. of Dick-positives after immunisation, the 42 per cent. of "turn-overs" being ascribed to traces of heat-labile toxin. It is of interest, too, that 17 per cent. of 6 Dick-negative subjects developed an allergic positive reaction after the inoculations with heat-stable toxin.

Twenty-three subjects immunised with heat-labile toxin showed in no instance an increase in the size of the Dick reaction to heat-labile toxin or Dick toxin after immunisation; 35 per cent., however, showed an increase to heat-stable toxin. Of 20 subjects immunised with heat-stable toxin 5 per cent. showed an increased reaction to heat-labile toxin, 20 per cent. to heat-stable toxin, and 10 per cent. to ordinary Dick toxin.

Summarising this section, from the standpoint of immunisation, Dick toxin partakes much of the nature of heat-labile toxin. When a course of injections of heat-stable toxin is given, either there is no effect on the skin reaction to Dick toxin or an allergic skin response develops.

No allergic reaction to Dick toxin appears to be produced after immunisation with pure heat-labile toxin. Allergy may, however, develop in some cases when Dick toxin containing more or less heat-stable endotoxin is used for the immunisation.

Immunisation with Toxoid (Anatoxin).

We have prepared toxoid by the addition of 0·4 per cent. formalin to streptococcus culture filtrate and incubating at 40° C. for one month. Thirty-nine per cent. of 36 subjects remained positive after four inoculations. However, on re-test with heat-labile toxin, only 17 per cent. were positive, the other 22 per cent. of positive reactors on the first test having apparently been allergic in character. On a further re-test with heat-stable toxin 94 per cent. were positive showing a marked allergy. Allergy is most pronounced in subjects who have received a full course of inoculations; the greater the number of S.T.D. injected, the greater the allergic response. Toxoid immunisation appears to give a higher percentage of allergic reactions than does immunisation with raw toxin (streptococcus culture filtrate).

Some Practical Applications in Connexion with the Dick Test.

(*a*) *Selection of strains.*—A good toxin-producer is essential so that a high dilution of the filtrate may be used for the Dick test. Low dilutions of toxins contain a relatively greater amount of the heat-stable constituent.

(*b*) *Culture media.*—It is important to avoid blood, serum, or other protein. We ourselves use 0·5 per cent. glucose bouillon.

(*c*) *Preparation of Dick control.*—Owing to the difficulty of getting a satisfactory control to ordinary Dick toxin which contains both heat-labile and heat-stable constituents, the advisability of testing all patients with both heat-labile and heat-stable toxins is apparent.

(*d*) *When and how to judge results of Dick test.*—We have already referred to the wide differences which occur in the rate of development and course of a positive Dick reaction. In some cases when the reaction is seen 24 hours after inoculation it is fading, in others it is increasing. Parallel tests with Dick toxin, heat-stable toxin, and heat-labile toxin will help one in many cases to assess the susceptibility or immunity of the patient.

Summary.

1. Experiences with the Dick test and active immunisation against scarlet fever in Manchuria are described.

2. Tests have been performed with the heat-labile and heat-stable constituents of Dick toxin described by Ando.

3. If the heat-labile toxin is used instead of ordinary Dick toxin a number of the inconsistencies of the Dick test disappear.

Baby Week Challenge Shields.—The National Baby Week Council, which annually awards two silver challenge shields for the most effective local baby week campaigns, announces that the Lady Astor Shield, reserved for competition among the great towns, has been won for the second time by the Kettering U.D.C. Ladies' Voluntary Committee for Infant Welfare, while Northampton Maternity and Infant Welfare Voluntary Association secures the second place. The William Hardy Shield, reserved for smaller areas, has been won by the Welwyn Garden City Health Council. The Hill and Cakemore (Worcs.) Infant Welfare Centre was second.

The Cost of Motor Accidents.—At the annual meeting of the Western Infirmary, Glasgow, recently it was reported that in 12 months the treatment of injuries caused by road accidents cost the three large Glasgow hospitals over £10,000. The Western Infirmary alone, from Jan. 1st to Dec. 16th, 1929, treated 222 in-patients and 212 out-patients suffering from motor-car accidents. The in-door patients had a total residence in the hospital of 4344 days, equal to a cost of £1737; in addition, 204 in- and out-patients injured in omnibus and tramcar accidents were treated. These transport accidents cost the infirmary during the year £2336 for in-patients alone.

Clinical and Laboratory Notes.

THE CEREBRO-SPINAL FLUID IN TUBERCULOUS MENINGITIS IN ADULTS.

By D. S. Murray, B.Sc., M.B., Ch.B. Glasg.,
PATHOLOGIST, LAMBETH HOSPITAL, LONDON.

Tuberculous meningitis in adults is not a common disease, and when it does occur is so often associated with obvious and previously recognised lesions elsewhere, especially in the lungs, that its diagnosis on clinical grounds is comparatively easy. Occasionally, however, it arises without such association, and must then be differentiated from other possible intracranial lesions. In this differentiation the cerebrospinal fluid (C.S.F.) is an important, and, as the following cases show, an almost infallible guide.

J. G. Greenfield states that most observers have failed to demonstrate tubercle bacilli in 60–70 per cent. of cases, but the records at Lambeth Hospital in the period covered by this series show that this figure can be greatly improved upon. In the 24 cases here reviewed, the C.S.F. was examined 32 times, and in all of these tubercle bacilli were found. In one case the first examination failed to show tubercle bacilli, but so convincing were the other features of the fluid that another specimen was obtained, and the bacilli were then easily found. Apart from the demonstration of the organisms, the general findings in the C.S.F. are of interest. The variations are wide, but when an average of the different results is taken, we get a picture of the C.S.F. in adult tuberculous meningitis as follows:—

Age.	Appearance of C.S.F.	Clot.	Protein.	Sugar.	Chlorides.	Cells per c.mm.	T.B.
Average Results.							
28	Clear.	+	0·27	Less than normal.	0·637	298	+
Variations Sometimes Found.							
15–60	Clear or yellow.*	+	0·1 to 0·6.	..	0·570 to 0·731.	31 to 984.	A few to abundant.

* Occasionally turbid.

From these figures it will be seen that the three factors of value in diagnosis are: (1) the presence of clot; (2) the level of the chlorides; and (3) the identification of the tubercle bacillus. The clot appears very soon after the fluid is withdrawn, but is best left undisturbed for 12–18 hours, by which time it is contracted, and can be handled more easily. It is a thin, delicate clot, usually suspended from the surface of the fluid or the side of the test-tube, and requires very careful handling. C.S.F. from patients with other diseases does also clot (the clot is indeed an indication of high protein level), but in no other pathological condition have I seen a clot with exactly the same characters.

Two separate samples of C.S.F. are always taken, and whenever there is any suggestion of meningitis, or where the cell count, which is done immediately the fluid is received, is more than 30 per c.mm., the tube is left entirely undisturbed until the next morning. If the condition is tuberculous the clot by that time will be sufficiently contracted to allow of examination. The test-tube is tilted, and with the platinum loop the clot is gently floated out on to a glass slide, allowing a little of the fluid to escape. The excess is taken up with blotting paper, and the slide is dried in the incubator. In transferring the clot to the slide it always tends to become twisted into a rather thin thread, which may be difficult to see through. The clot may also adhere to the loop, and practice is necessary to carry out the manœuvre correctly. I have often been indebted to the skill of my senior technician in handling a clot in which tubercle bacilli were very scanty.

When the clot is dried it is stained by the usual Ziehl-Neelsen method, and the organisms searched for. This may be a long process, and every part of the clot must be examined thoroughly before the search is given up. Twenty to forty minutes may be spent before a single organism is found. Five cases will illustrate how important the identification of the organism may be.

The Cases Described.

1. A. B. C., male, aged 60. Admitted March, 1923, with a history of head injury three days previously. Examination showed indefinite signs and probable neck rigidity. Lumbar puncture showed a clear C.S.F., in which cells numbered 122 per c.mm. On the fluid being set aside it clotted, and T.B. were found in the clot. Chlorides were 0·672 per cent. At post-mortem old and caseating lesions were found in both apices.

2. D. E. F., male, aged 17. Admitted with diagnosis of encephalitis lethargica. The patient had been ill for three weeks with sickness and headache. Signs were ambiguous, but the patient had a positive Kernig. The C.S.F. was straw coloured, and gave a count of 371 per c.mm. Cells showed 7 per cent. polymorphs and 93 per cent. round cells. A clot formed, and after prolonged search a few tubercle bacilli were found. Protein was 0·22 per cent. and chlorides 0·585 per cent. No autopsy was permitted.

3. G. H. I., female, aged 29, married. Had been in a sanatorium one year before admission, but signs were slight and sputum was never positive. Had been losing weight for four months. Headache was the first sign of the final illness, and persisted for ten days. Patient was admitted in semi-conscious condition. The C.S.F. was clear and clotted before reaching the laboratory. The clot showed 30 per cent. polymorphs and 70 per cent. lymphocytes, and search showed a few T.B. Next day the C.S.F. was again examined. It was very slightly turbid, and the cell count was 517 per c.mm. Protein was 0·2 per cent. and chlorides 0·630 per cent. Tubercle bacilli were very easily found. At autopsy a typical tuberculous meningitis was present, but no other definite lesion was found. The apex of the right lung was scarred, and histologically gave the picture of tuberculosis.

The remaining point of diagnostic importance is the level of the chlorides. The following case, which has already been mentioned, shows that this may be diagnostic.

4. Mrs. J., aged 31. Patient admitted Jan. 29th, 1928, after being feverish for one week. The examination of C.N.S. revealed no abnormality, except that the pupils were sluggish. Headache was persistent and lumbar puncture was done. The fluid clotted, but tubercle bacilli could not be found. Protein was 0·2 per cent. and chlorides 0·702 per cent. Cells were mainly round cells but a few polymorphs were present. A diagnosis of tuberculous meningitis was suggested. Next day the C.S.F. showed protein 0·12 per cent., chlorides 0·637 per cent. Tubercle bacilli could not be demonstrated as the clot was broken up. Nevertheless the diagnosis was considered definite, as the cells were few in number, and the chlorides were lower than is usual in any other condition. Two days later the C.S.F. gave: protein 0·15 per cent., chlorides 0·660 per cent. The clot showed both round cells and polymorphs and tubercle bacilli were easily found. No post-mortem was allowed, but in life no other evidence of tuberculosis was found.

5. Mrs. K. L., aged 20. Admitted July 29th, 1929, with diagnosis of lobar pneumonia. Had been ill 11 days, with cough and difficulty in breathing. Had fits at onset of illness, but no abnormality was noted in C.N.S. Three days later patient became drowsy, and complained of pain in the neck. The C.S.F. was sent to the laboratory without any indication of the diagnosis, and gave: protein 0·2 per cent., chlorides 0·614 per cent., cells 31 per c.mm. Here the chlorides were considered diagnostic, and the fluid was set aside. A very small clot formed, and was examined with great difficulty. A few tubercle bacilli were found after prolonged search. Three days later the C.S.F. chlorides were 0·601 per cent., and tubercle bacilli could be found easily. Four days later, a few hours before death, protein was 0·4 per cent., chlorides 0·601 per cent. Cells 984 per c.mm. and tubercle bacilli were abundant.

The protein is not of diagnostic value, but the relation between it and the cell count is. When the protein is high, yet the cell count is no more than 100–300 per c.mm., the diagnosis of tuberculous meningitis at once arises. Syphilitic lesions seldom show so many cells, while much higher counts are given by septic meningitis. The cells are usually predominatingly small lymphocytes, but polymorphs are always present, and may reach as much as 50 per cent.

All the cases here dealt with were fatal, and at autopsy tuberculous lesions apart from the meningitis were usually found, but the most common was a miliary tuberculosis, of which the meningitis was a concurrent part. In a few cases the other lesions were slight and unsuspected—e.g., a nodule in the kidney or the lungs. No case was found of tuberculoma of the brain, but in all the lesion was a typical tuberculous meningitis. It may be concluded, therefore, that in a C.S.F. showing a clot, chlorides near 0·640 per cent. and a cell count not too high, tubercle bacilli should usually be found and a diagnosis of tuberculous meningitis made.

I am indebted to my colleagues at Lambeth Hospital for the use of their notes on the above cases.

AN INHALED FOREIGN BODY EXTRUDED THROUGH THE CHEST WALL.

By E. Hayling Coleman, M.D. Camb.,
HON. PHYSICIAN TO THE ROYAL HOSPITAL, WOLVERHAMPTON;
AND
Vincent Patrick, F.R.C.S. Eng.,
HON. SURGEON, STAFFORDSHIRE GENERAL INFIRMARY.

It is unusual for a foreign body which enters the lung through the upper air passages to be spontaneously extruded through the chest wall. This was the fate of an ear of a common grass, resembling in appearance an unripe ear of barley, which was accidentally inhaled by a patient of ours. In former days small boys used to insert these grasses, stalk first, under the wrist of a jersey-sleeve, when the movements of the body acting on the stiff bristles of the grass would cause the ear to be propelled up the arm and to reappear in some distant situation. The modern small boy, however, does not appear to be content with this simple pastime; in Cannock, at least, a more dangerous game is played, one boy standing with open mouth while his playfellows aim grass-ears at the target so presented. In this case a well-aimed grass evidently passed into the upper aperture of the larynx, and by reason of the arrangement of its bristles passed inevitably onwards through the larynx, trachea, bronchi, lung, and chest wall.

The inhaled foreign body.

The patient, aged 3½, was sent into the Royal Hospital, Wolverhampton, by Dr. T. Hutchinson, of Cannock, on July 28th, 1929. About a month prior to admission he had taken part in this grass-throwing game, and shortly afterwards developed a persistent cough. For a fortnight before admission he had been ill at home, with a temperature ranging up to 103° F. On July 23rd he coughed up some blood, and a swelling developed on the chest wall in front of the angle of the right scapula. While dressing this swelling on July 28th the district nurse noticed what she took to be the end of a suture projecting from its centre. This she seized with forceps, and withdrew an ear of grass 1¾ inches long. The child was then sent into hospital.

On admission, and for the first three days, the child's condition remained fair, temperature 99°, pulse 110–120, respirations 28–32. The right base was dull on percussion, and the breath sounds were much diminished. There was a small sinus over the eighth intercostal space on the right side in the posterior axillary line, from which there was a slight purulent discharge. This pus showed a mixed infection, including streptococci, pneumococci, and *M. catarrhalis.* A radiogram showed increased density at the right base; but exploration with a needle withdrew no fluid. On July 31st he suddenly had a bad fit of coughing, and brought up about a pint of exceedingly foul pus; this left him very collapsed, and for the next three days he was very ill indeed, the pulse ranging from 140–160, respirations 40–48, and temperature up to 102°. During this period camphor and other stimulants were employed hypodermically, and the chest aspirated again without result. On August 4th he was a little better, temperature 99°, pulse 136, and respirations 32, and an injection of lipiodol was made through the small sinus to determine if possible the extent of the abscess cavity in the chest. A radiogram showed globules of lipiodol resting on the upper surface of the diaphragm and that none had entered the lung substance. It was deduced from this that the lung was not adherent to the chest wall, and that most of the pus was in the pleura, and not in an abscess of the lung as had been suspected. Accordingly the same evening a portion of the ninth rib was resected under local anæsthesia, and the empyema drained. The temperature fell rapidly to normal.

The child made a steady recovery; the tube was removed on Sept. 5th, and the child went to a convalescent home on Sept. 9th. Seen as an out-patient on Nov. 9th he seemed very well but there was still a little discharge from the wound; a month later the wound was completely healed.

ORIENTAL SORE TREATED BY BERBERINE SULPHATE.

AN ANALYSIS OF FIFTY CASES.

By P. V. Karamchandani, M.B. (I.M.S., Retd.).

In a previous paper [1] I welcomed berberine sulphate as a remedy which deserved to be universally tried. I propose now to give the results of further trials with berberine sulphate in Oriental sore during the last two years.

Fifty cases of Oriental sore, multiple as well as isolated, were treated between Dec. 16th, 1927, and July 19th, 1929. Hypertonic and isotonic saline dressings were not applied. In some cases the injections were given twice a week to see whether bi-weekly injections had any effect in shortening the course of disease, and also if any untoward effects occurred locally. It was found that they had no advantage over the weekly ones, nor were any untoward effects noticed.

The average period of cure per case worked out at little more than 17 days, and the average number of injections at three. If injections had been given at weekly intervals the latter figure would have been much lower. Even these figures in my opinion compare favourably with the results achieved by the use of intravenous tartar emetic. I have come to the conclusion that in berberine sulphate we have a better drug than tartar emetic for isolated sores. Of course, for multiple sores treatment by berberine sulphate is rather tedious. My earlier limited experience has, however, been modified in one respect—viz., that an injection affects sores over an area of about three square inches. The effect of the drug, I now find, is purely local.

The following points are worthy of consideration: (1) The drug should be fresh, because it seems to lose potency with age. (2) The solution should be prepared fresh each time for immediate use and prepared solutions should not be kept in stock. (3) Hypertonic and isotonic saline solution dressings are very strongly recommended in conjunction with the injections. (4) No untoward effect whatsoever has been noticed from the use of the drug. (5) A dose of one-third of a grain, instead of one-quarter of a grain, in 1·5 c.cm. has been found to give better results.

A CASE OF PURPURA HÆMORRHAGICA ASSOCIATED WITH SCARLATINA BENIGNA.

By Laura Trewby, L.R.C.P. & S. Edin.,
ASSISTANT MEDICAL OFFICER, LEEDS CITY HOSPITAL.

The patient, a girl, aged 18 years, was admitted to the City Hospital, Leeds, on Oct. 4th, 1929, suffering from scarlet fever. She looked healthy. There was no history of rheumatism, and nothing abnormal in the family history; she had had measles and whooping-cough in infancy.

She was admitted on the fourth day of the disease, and appeared to have a typical attack of scarlatina benigna. The symptoms included a temperature of 102·4° F. on admission, a moderately well-developed punctate erythema, moderately injected throat with rather large tonsils, some follicular deposit being present, no adenitis, and a faint trace of albuminuria on the day of admission only. The heart and lungs appeared normal. On the sixth day she complained of slight rheumatic pains about the shoulders. This passed off within a few days. Desquamation occurred on the twelfth day of the disease. As her progress appeared to be satisfactory, she was allowed up on the 22nd day, but had to return to bed, as she vomited twice and developed a temperature of 99·6°. On the 23rd day she complained of rheumatic pains which attacked successively her hands, right elbow, left foot, back, left elbow, and left knee. This continued during the 24th day. The joints appeared to be swollen. On the 25th day the pains were easier, but the swelling persisted. Patches of purplish staining appeared on the trunk and extremities. There was a complete left and a partial right subconjunctival ecchymosis. The temperature reached 101·4° at this stage. It was suspected that the joint condition was due to effusion of blood. On the 26th day fresh purpuric areas appeared. One involved the left anterior quadrant of the tongue and formed a rather prominent swelling. In the course of the forenoon bleeding developed from the mucous membranes of the mouth. By midday she became very restless, flinging herself about the bed. Semi-consciousness followed and death ensued at 8 P.M. An autopsy was not permitted.

C. B. Ker states that he had only seen a few cases of purpura hæmorrhagica, and these in septic cases, and usually supervening in the third week. J. D. Rolleston and others have described cases of a rapidly fatal type of the disease known as purpura fulminans, in which the ecchymoses are large and inflammatory, and in which no bleeding from the mucous membranes occurs. J. J. Phelan has reported a case of purpura fulminans occurring in scarlatina benigna, and states that in the literature he can find no definite evidence of a similar case.

The case reported differs from Phelan's case in two particulars, the less rapid course and the terminal development of hæmorrhages from the mucous membranes.

I am indebted to Dr. J. S. Anderson, medical superintendent of the Leeds City Hospitals, for permission to place this case on record.

King George Hospital, Ilford.—This proposed hospital, which will serve the population, amounting to 50,000, of Ilford, Barking, Becontree, Dagenham, and Manor Park, will take the form of an enlargement of Ilford Emergency Hospital from 70 to 300 beds. The Prince of Wales pointed out that with the exception of this small institution there is no voluntary hospital along Thames-side between Barking and Tilbury, and it was mainly to include this area that five years ago the orbit of the King's Fund was extended from 9 miles round Charing Cross to 11 miles round St. Paul's. That Fund has already made a grant of £10,000 out of the Wells legacies, and has now granted a further £10,000 from the Thank-offering Fund. With £2000 for the extension of the old building and £2000 from the ordinary distribution for 1929, the King's Fund has thus provided a total of £24,000. The Ford Motor Company, which has a factory site at Dagenham, has given £5000, Mr. Henry Ford and his son, Mr. Edsel Ford, have each contributed £2000, and Sir Percival Perry, the chairman of the company, £1000.

Medical Societies.

ROYAL SOCIETY OF MEDICINE.

SECTIONS OF TROPICAL MEDICINE AND PATHOLOGY.

TROPICAL DISEASES ARISING FROM DIETETIC DEFICIENCY.

A COMBINED meeting of these Sections was held on Jan. 7th, when the chair was occupied by Prof. J. B. CHRISTOPHERSON, President of the Section of Tropical Medicine.

Prof. J. W. B. MAGAW said there were three main forms of dietetic deficiency in the tropics: first, shortage of food as a whole; secondly, shortage of available proteins; thirdly, shortage of vitamins. Many millions of the inhabitants of tropical countries lived on the borderline of starvation, and when harvests were bad many suffered from actual starvation. The problem, in a broad way, therefore became one of adjustment of the population to the food supply. It should be emphasised that research workers could do little to improve the conditions of human existence so long as these efforts were nullified by a progressive increase in population. The well-being of the human race must depend on four supports: (1) the production of food and other necessities; (2) the control of reproduction; (3) the prevention of disease; (4) the maintenance of security. Most of the people in the tropics lived short of proteins. Mackay had found but little deficiency of vitamins in the diets which he investigated, and had considered that if there were adequate protein in the food the vitamins would take care of themselves to such an extent that their apparent shortage would not be a serious problem. The subject of vitamin B deficiency was sufficient to fill an evening's discussion. He did not agree with those workers who said that beri-beri was caused by a deficiency in the diet of vitamin B, or that all other theories of the causation of that disease had died a natural death. Some workers denied that deficiency could account for outbreaks of the disease which they had studied. Many believed there was a factor in addition to avitaminosis. In the Far East beri-beri was strikingly associated with a diet of over-milled rice, and peripheral neuritis was a notable feature. Fowls and other winged creatures developed this neuritis, and it could be cured or prevented by giving vitamin B. Beri-beri in humans living on over-milled rice could be cured or controlled by the substitution of par-boiled rice. Attempts had been made to reproduce beri-beri in human beings, using volunteers from among the jail population in the Philippines. These experiments showed that a monotonous diet which was poor in calories, in available proteins and in vitamin B, caused a vitamin disturbance which was suggestive of beri-beri. It was found difficult to devise a diet lacking in vitamin B, but satisfactory in all other ways. There was really very little reliable evidence of a uniform association between human beri-beri and vitamin deficiency. Prof. Magaw went on to describe several outbreaks of epidemic dropsy. Two authorities were unable to exclude this disease from the beri-beri group. It often appeared as an explosive outbreak among people who were living on the same diet as usual; there was no reason for regarding this disease as an avitaminosis. Beri-beri was a name which had been used for many years to designate certain disease manifestations, mostly associated with the use of a rice which had been stored for a long time after manufacture. There might be two or more diseases in the beri-beri group, but they had not yet been differentiated with certainty. Probably one of those diseases was caused by a poison which was formed in rice stored in damp and hot rooms. He admitted that some of the diseases entitled to be included in the group were due to a deficiency, chiefly of vitamin B. An attempt ought to be made to differentiate the diseases in the group; one should not be satisfied with a hypothesis which invoked several causes for a single disease. He did not accept the idea of endocrine deficiency as a satisfactory explanation of any disease. If endocrine glands were deficient, the question to be answered was why they had become disordered. Probably the endocrine deficiency was an effect, not a cause. Practitioners need not be depressed because causation of beri-beri was still obscure; their duty was clear—namely, to cut out rice from the diet, so ensuring that poisons residing in rice were eliminated; and to ensure that the diet was nourishing and that it included vitamin B.

Dr. G. MARSHALL FINDLAY said it was possible to produce various types of inanition. One was the quantitative type, in which all the known factors were present in the diet, in complete or incomplete amounts. Qualitative deficiencies, however, were the most important, and the lack of certain amino-acids was most important of all. The aromatic amino-acids seemed to be essential in the diet. In the course of a review of our present knowledge, Dr. Findlay said that if rats were placed on a complete diet, except that the sole source of protein was represented by dried egg white, they developed dermatitis, the hair fell out, and they had a kangaroo-like attitude when they walked. The pathological changes were identical with those seen in children with "pink disease," but never older than 3½ years. The condition known as hunger œdema, seen, for instance, in Russia in 1921, had never been produced in animals, but was probably due to protein deficiency. Epidemic dropsy seemed to occur only in rice-eaters, whereas beri-beri often occurred in those who had never eaten rice, but suffered from a deficiency of vitamin B1. In association with epidemic dropsy there was often an acute exanthematous rash, and also glaucoma, which had not been described in association with true beri-beri. The changes in an early condition of pellagra, said Dr. Findlay, were described as a degeneration of the cells of the central nervous system, and a collection of lipoid pigment in the cells; but the degenerative changes in the cord were not usually found in human pellagra until the condition was very marked.

Discussion.

Dr. H. B. DAY said that pellagra bore the same relation to the consumption of maize as beri-beri did to the consumption of rice. No one had succeeded in transmitting pellagra. One of its earliest symptoms was diarrhœa, but unless there was a complicating infection there was nothing characteristic about the stools. The cause of pellagra, he thought, was something which was related to nutrition, chiefly of the ectodermal structures. The problem in man and in animals was not the same. It had been suggested that with a larger protein consumption, more vitamin B was required than when the protein was cut down to a minimum. That might explain the vagaries met with in the condition.

Dr. G. W. BRAY gave the meeting his experiences in the mandated islands of the Pacific bordering on New Guinea. Here infantile beri-beri was very rife, and the mortality among the newly born was about 50 per cent. The native population did not eat rice, but lived on fish and native fruits. Fermented liquors were denied them. The cases were formerly diagnosed as stomach trouble, marasmus, broncho-pneumonia, &c. Death usually took place from the ninth to the twelfth week after birth, the death-rate being least when the rainfall was heaviest. Infants, apparently well, would suddenly vomit, scream, and die within five minutes. In most of the cases the illness did not last longer than 24 hours. The yeast found in the sap of the coconut palm was found to cure this condition, and the infantile mortality, which formerly was 400 per 1000, was now about 70, or little more than in England. It was the custom of the mothers at the time of the birth to eat very little but to drink a good deal of sugared water. Neither white flour nor polished rice was allowed to be sold now, and the drinking of so much sugar-water was discouraged.

Dr. Tertius Clarke said that the disease he encountered in Malaya was true beri-beri, but that in India was not. When par-boiled rice was substituted for the polished kind the disease ceased.

Dr. W. R. Aykroyd spoke of beri-beri among the inhabitants of Newfoundland and Labrador, who were living on staple white flour. The beri-beri seen there was associated with polyneuritis, myocarditis, and occasionally with œdema, and it occurred in people who were living in conditions of marked malnutrition —people who for months were confined practically to refined white-flour bread, with a small addition of salt meat or fish and some molasses. When a better diet was available the cases decreased in number. In these regions there seemed to be a close relation of the disease to absence or deficiency of vitamin B 1.

Dr. Hugh Stannus suggested that besides some deficiency there was operative some active factor in the diseases such as beri-beri, though its action was masked. The onset of rickets could be materially helped by giving large quantities of oatmeal. He would like to know whether various species of animals made use of different amino-acids, or were they common to all species?

Dr. Kingston Barton asked why the infants in Polynesia, who continued to be breast-fed for many months, failed so soon. Owing to the continuation of practical starvation of the mother probably her milk was at fault.

Dr. G. W. Theobald said he came from Siam, where it was impossible to knock the patient off rice. His patients were pregnant women, who in every case had beri-beri of the dry type. Their diet was not altered, except to substitute unpolished for polished rice, and they got well. He had seen some of Colonel McCarrison's pigeons, and he did not see much difference between the polyneuritis of those pigeons and the dry beri-beri of his own patients. The result of the white man's incursion into Siam was that rice was polished solely for the European market. Three years ago a congress under the auspices of the League of Nations was held in Singapore to try to stop this polishing, but the Government opposed, saying that unless the rice were polished there would be no market for it in London. Therefore the industry was still flourishing.

Replies.

Prof. Magaw, in reply, said it would not be a surprise to learn that a toxin was excreted in the mother's milk in the cases referred to by Dr. Bray. Glaucoma occurred in epidemic dropsy, but not in beri-beri, though the French called attention to a scintillation of the eyes and a dimness of vision associated with the latter disease. Epidemic dropsy was usually explosive, but not always. It was always difficult to get a sample of the actual rice implicated in an outbreak, for when inquiry was made the dealer took fright and disposed of the rice elsewhere. In the larger proportion of cases pellagra occurred among maize-eaters. The behaviour of beri-beri suggested the activity of an irritant toxin which entered the body through the gastro-intestinal mucous membrane.

Dr. Findlay, in reply, said that when scurvy was experimentally produced in utero the mother might not be suffering from the disease; and he thought it was safer in the conditions now being discussed to assume there was a deficiency which was affecting the mother to a slight extent, but was shown definitely in the infants. The dimness of vision, &c., in beri-beri suggested deficiency in vitamin A, since such deficiency caused night-blindness and other conditions of the kind. There was much evidence that absence of vitamin B 1 interfered with the metabolism of the organism in a number of ways.

The Chairman said his own experience of tropical disease was in the Soudan, where there was practically no pellagra at all, though in the contiguous country of Egypt it was one of the most serious of the national diseases. In the Soudan millet was the staple food, while in Egypt the food was maize. Much still remained to be learned concerning both pellagra and beri-beri, and when India and Egypt attained to the larger measure of independence at which they were striving he hoped the researches so carefully made would be continued, to the benefit of their population.

PATHOLOGICAL SOCIETY
OF GREAT BRITAIN AND IRELAND.

A meeting was held on Jan. 3rd and 4th in the Bland-Sutton Institute at the Middlesex Hospital, Prof. J. McIntosh in the chair.

F. W. Andrewes (London) pointed out that the immediately preceding cultural conditions might greatly influence the agglutinability of hæmolytic streptococci.—C. E. Dukes (London) gave an account of several cases of polyposis intestini with their family trees, showing that the condition is familial, inherited apparently as a mendelian dominant, more frequent in males than females, and ending in carcinoma in two-thirds of the cases unless prophylactic excision of the large bowel has been done.—J. H. Teacher (Glasgow) showed a specimen of carcinoma of the gall-bladder from which about 100 secondaries had been implanted in the mucosa of the intestine though embolic dissemination with specific localisation could not be excluded; there was widespread lymphatic metastasis. —E. H. Kettle (London) described a case which broke the rule that chronic ulcer of the duodenum never leads to cancer.—W. Cramer (London) had tried a great variety of experiments to look for evidence that mouse carcinoma or sarcoma was transmissible without living cells; some of the results, especially with sarcoma, were suggestive, but none conclusive that this might sometimes happen.—T. Lumsden (London) had had an American strain of mice (which in Buffalo develop carcinoma of breast in 94 per cent. of the females), without obtaining any such excess of tumours; he described also a number of observations on the subcutaneous nematodes of mice.—Helen Chambers and Gladwys Scott (London) summarised their experience of many years in the propagation of the Jensen rat sarcoma; the young born of animals in which the tumour had spontaneously regressed were more resistant than usual.—F. C. Happold (Leeds) discussed the correlation of the oxidation of certain phenols and dimethylparaphenylenediamine by certain bacteria.—J. B. Duguid, Marjorie Duggan, and J. Gough (Cardiff) had endeavoured to produce arterial degeneration by giving excessive quantities of irradiated ergosterol by the mouth. Little effect was obtained in rabbits, more in cats; in rats, abundant calcification was obtained if they were fed on a vitamin-free diet, with or without the addition of cod-liver oil and marmite, but not if they received an ordinary mixed diet. Calcification was preceded by degeneration. Cramer and Cameron had obtained similar results.—M. J. Stewart (Leeds) found that the "curious bodies" of human pulmonary asbestosis could be produced in guinea-pigs by the subcutaneous inoculation of asbestos dust, the fibres acquiring the characteristic nodular accretions.—S. L. Cummins and A. F. Sladden (Cardiff) showed the importance of estimating the amount of silica in the lungs of coal-miners suffering from pulmonary fibrosis.—J. G. Greenfield (London) described the changes in the central nervous system in two cases of encephalomyelitis following mild febrile illness ("influenza") one fatal after four days from broncho-pneumonia, the other after seven weeks from cystitis. Perivascular demyelination was very marked.—J. McIntosh (London) maintained that the characteristic histological change in vaccinal encephalitis (rabbits) was an endothelial, not a lymphocytic, reaction, and that in this way the disease differed from post-vaccinal encephalitis in man. Hurst said that his experience in monkeys bore this out.—W. M.

Crofton (Dublin) said that he had isolated a small Gram-negative bacillus (possibly the same as that obtained by Copeman many years ago) from vaccine lymph and cases of small-pox and that vaccination with it protected rabbits against vaccinia.—R. W. Fairbrother (London) prepared a serum in horses by massive dosing with the brain-tissue of monkeys experimentally injected with poliomyelitis, and found that it had a definite, but low, power of neutralising the virus.—G. S. Wilson (London) described four races of *Bacillus aertrycke* isolated from one culture, which showed permanent differences in colonial form, morphology, agglutinability, and virulence. In shape they varied from long filamentous bacilli to short coccoid forms.—W. Mair (London) discussed the difficulties and discrepancies of testing the virulence of diphtheria cultures, and maintained that they could not satisfactorily be divided into virulent and avirulent; the existence of intermediate slightly virulent stains had to be recognised.—H. J. Parish and C. C. Okell (London) had found that young rabbits were less susceptible than larger animals to the scarlet fever streptococcus and its toxin.—Muriel Robertson and A. Felix (London) by inoculation with heated bacilli prepared an anti-vibrion-septique serum, which had no antitoxic power, but a considerable capacity of preventing death in animals inoculated with spores *plus* calcium chloride as an activator; unlike the antitoxin, this antibacterial power is type specific.—D. Nabarro and A. G. Signy (London) reviewed a year's experience with dysentery infections at Great Ormond-street Hospital; Flexner Z and Sonne bacilli were isolated many times; a considerable proportion of the cases contracted infection while in hospital.—S. Ellingworth, F. C. Happold, J. W. McLeod, and D. P. Priestley (Leeds) showed that the gonococcus could be isolated from the female genital tract more certainly by using media which had not been heated much during preparation, and by using the tetramethyl method of distinguishing the colonies.—Juliette Marchal (London) demonstrated a new virus disease of mice causing lesions on the feet and in the viscera.—F. T. Grey (London) showed his colour-index ratiometer and proteinometer.—D. H. Patey, R. W. Scarff, and S. L. Baker (London) showed various pathological specimens and a series of breast carcinoma correlating histological structure and malignancy.—H. J. B. Fry (London) showed lymphadenomatous ulceration of the intestine, and J. S. Dunn (Manchester) the infiltration of squamous epithelium by mucous carcinoma.

BRIGHTON AND SUSSEX MEDICO-CHIRURGICAL SOCIETY.

A MEETING was held on Jan. 2nd, Dr. W. BARRINGTON PROWSE, the President, in the chair.

Mr. J. R. GRIFFITH read a paper entitled

The Technique of Local Anæsthesia.

He said that he uses Labat's syringe and needles and Corbiere's neocaine, and then described the methods that he uses for anæsthetising the upper arm in out-patients and in-patients. He anæsthetised the fingers by blocking the digital nerves at the webs, infiltrating the dorsal aspect of the finger at the same time in order to cut off the radial branches. The hand was anæsthetised by infiltrating the median and ulnar nerve at the wrist, and by making a ring of infiltration in the skin round the wrist in order to cut off the superficial fibres running in the subcutaneous tissues to the hand. In dealing with Colles' fracture, Mr. Griffith said that he had found local infiltration round the site of the fracture unsatisfactory. Brachial plexus block requiring too long a wait, he now relied on blocking the ulnar, median, musculospiral, and musculocutaneous at the elbow, at the same time blocking the superficial nerves with a ring of infiltration at the same level. The technique of brachial plexus block was then described. By this method the whole arm was anæsthetised except a small area in the axillary part supplied by the intercosto-humeral. The brachial plexus consisted of a number of thick, tough nerves, and required a large amount of 2 per cent. solution to soak through to the deeper fibres. It was important, therefore, to distribute the fluid throughout the whole length of the plexus. The injection was made in three places through a single puncture which was situated 1 cm. above the middle of the clavicle. The first injection was made where the cords cross the first rib; the second was made at the origin of the roots from the intervertebral foramina; and the third injection was made below the level of the first rib, where the nerves separate from the cords. All these injections could be very quickly and easily carried out; several patients could be injected one after the other and their treatment carried out in turn. Both the preparation for and the recovery from general anæsthesia was avoided, and the patient was able to return home without discomfort. The anæsthesia gave plenty of time, and the very perfect muscular relaxation that was obtained made the reduction of fractures and dislocations comparatively easy. At the same time the patient was able to coöperate. For instance, the patient with fracture of the neck of the humerus could sit on a stool while the arm was fixed in abduction with plaster-of-Paris. Where the injury was of the hand and fingers, the patient could voluntarily move the joints, showing whether the mechanical disability had been completely overcome.

Mr. Griffith then described the method of local infiltration and field block, stressing the importance of systematically infiltrating the whole thickness of the tissues.

The method of anæsthetising the maxilla and the tongue used for patients was described. This consisted in the infiltration respectively of the tissues in the sphenomaxillary fossa, and of those in proximity to the inferior maxillary division of the fifth nerve. Mr. Griffith pointed out that this anæsthesia was comparatively easy to induce, since the solution had only to be placed near to the nerve. For operations on the tongue the glossopharyngeal nerve was blocked by infiltrating the back of the tongue through a puncture above the symphysis of the hyoid bone. Mr. Griffith thought that this technique would prove very useful when radium needles were used, for it did away with the discomforts and dangers associated with recovery from general anæsthesia. Rib-resection under local anæsthesia was then described and its advantages stressed. The technique of paravertebral block associated with splanchnic block was demonstrated, the splanchnic block being carried out from behind. The perfect relaxation that this procedure gave was of the greatest assistance, but Mr. Griffith admitted that he had usually to rely on his anæsthetist to relieve the patient from pain, although only a very small quantity of anæsthetic was necessary as a rule. In dealing with the lower abdomen, pelvis, and legs he used intrathecal block, the main disadvantage of which he found to be the shortness of the anæsthesia. In concluding his paper, Mr. Griffith dealt with the technique of caudal block, and insisted on the importance of using a large quantity of fluid, and also of making certain that the needle was actually in the spinal canal.

A film illustrating the technique of Mr. Waugh's operation for tonsil enucleation was then shown. The film had been specially taken by a representative of the Kodak Company at the Children's Hospital, Brighton. It showed the details of the operation, and included diagrams showing the blood-supply of the tonsil.

MANCHESTER'S ARTIFICIAL SUN.—The first public artificial sunray centre in Manchester has been opened at the Whitworth Baths, Ashton Old-road, Openshaw, by the Bath Committee of the corporation. Three quartz lamps have been installed and will be operated by specially trained attendants. The cost of the treatment will be 2*s.* for one bath, 4*s.* 6*d.* for three, and 7*s.* 6*d.* for a course of six.

Reviews and Notices of Books.

RICKETS, OSTEOMALACIA, AND TETANY.

By ALFRED F. HESS, M.D. New York. London: Henry Kimpton. 1930. Pp. 429. 25*s.*

THE publication of a really comprehensive treatise on rickets is an event, and no one could have been more competent to undertake this arduous task than Prof. Hess. The volume which he has produced will be of the greatest importance in medical literature, and will interest and instruct a wide circle of readers. The whole story of rickets is taken up from the earliest evidence of its existence, and traced throughout the history of medicine up to the present day. In his historical survey the author has been at pains to do justice to the contribution of Daniel Whistler, which he considers to have been somewhat unfairly depreciated by many writers on the history of medicine. In a chapter on the geographical distribution of rickets the conflicting evidence adduced from various countries is reviewed; Prof. Hess concludes that while no country is devoid of rickets, its incidence corresponds in general to the countries deficient in sunlight, subject to some qualifying influences, such as industrialism. The experimental induction of rickets in animals is described shortly in a special chapter, but is frequently referred to in later sections; the ætiological factors are discussed fully in one of the most attractive chapters in the book. Prof. Hess believes that heredity is at the most a minor factor seldom operative, but that a constitutional predisposition to the disease does exist. His summary of the question is that the dominant factor is sunlight; that the dietetic factor is important, and is as yet but imperfectly understood; and that the growth-rate is a factor of importance which must be regarded as determining as well as predisposing. The section on metabolism in rickets will be of exceptional value as a guide to a voluminous literature.

Prof. Hess emphasises the reserve with which the results of chemical experiments must be accepted, and doubts whether the pathogenesis will be solved by these means; but he has greater hopes of those studies which include the organic constituents of the tissues. The chapters on pathology and symptomatology are mainly descriptive, and contain admirable illustrations. In discussing diagnosis, stress is laid on the caution which should be observed in accepting craniotabes as evidence of rickets. The chapters on osteomalacia and tetany deal with the clinical features and biochemical characteristics of these disorders, and also their relation to rickets. Of particular interest is the author's account of the pathogenesis of tetany, and the conflict of opinion on the significance of total and ionised calcium values. While convinced that a true (uncompensated) alkalosis does not occur, he admits that a trend in the direction of alkalosis tends to the induction of tetany. There is a comprehensive bibliography, arranged in correspondence with the chapters, and this adds greatly to its value.

The volume contains considerably more material than might appear from its size, for it is closely printed. One of its most admirable features is the balanced and impartial manner in which divergent views are depicted, and the fairness with which Prof. Hess has presented opinions not his own. The work will be found essential to all who are studying the subject, and must occupy an important place in the literature of pædiatrics.

THE CEREBRO-SPINAL FLUID.

Le Liquide céphalo-rachidien. By Dr. RISER, Professeur agrégé à la faculté de Toulouse. Paris: Masson et Cie. 1929. Pp. 250. Fr.28.

THIS monograph deals with the physio-pathology of the subarachnoid and ventricular spaces, and is largely a critical review of the new methods of exploration of these spaces by injections of air, coloured substances, and lipiodol. Of this aspect of the cerebro-spinal fluid the Toulouse school, under the leadership of Prof. Cestan, has made a special study, and Riser's book is largely based on this work. The results of experiments and observations undertaken at Toulouse have almost entirely confirmed the work of the American physiologists, but have also amplified this in several ways. Thus it has been found that absorption of cerebro-spinal fluid in man takes place, not only by the arachnoidal villi, but through the walls of all the cerebro-spinal veins. Riser has also confirmed in man the observation that there is practically no absorption by the perineural lymphatics. Another point in human physiology which seems to be new is his manometric observation of the rate at which the cerebro-spinal fluid is normally secreted. In the majority of subjects he found that if, after recording the pressure, 20 to 30 c.cm. of cerebro-spinal fluid were drawn off it took from two to three hours for the pressure to be restored to the original level. This restoration was often slower but was rarely faster. It seems, therefore, as though about 10 c.cm. of cerebro-spinal fluid were formed every hour, under conditions of repose. This method is indirect, but it probably gives a better index of the true state of affairs than the rate at which dye-stuffs are eliminated from the subarachnoid space, which has suggested a considerably more rapid formation and absorption of fluid.

The author's wide experience and sound judgment are shown in the sections of the book that deal with the localisation of lesions of the nervous system by injections of air, lipiodol, and coloured solutions. Two procedures which he specially recommends are little used in this country; the injection of 5 c.cm. of air by the lumbar route to determine spinal block, and the intraventricular injection of phenol-sulphone-phthalein in hydrocephalus and subsequent colorimetric examination of the urine, either with or without an examination of the cisternal fluid, to determine the degree of obstruction. For the localisation of spinal tumours he prefers heavy lipiodol by the lumbar route to either the cisternal injection of heavy or the lumbar injection of light lipiodol. Encephalography is not recommended but ventriculography, if not more than 20 c.cm. of air are injected slowly, he considers a safe and useful procedure. Comparatively little space is devoted either to the examination of the cerebro-spinal fluid or to the changes in the fluid in disease, but in these sections, as elsewhere in the book, what is said is well said and worth saying.

If more space were devoted to these subjects and the arrangement of subject matter were rather more formal this would be by far the best text-book we possess on the cerebro-spinal fluid. As it is it contains so much valuable information at so low a price that it should be assured of a wide circulation.

CLINICAL METHODS.

A Guide to the Practical Study of Medicine. Ninth edition. By ROBERT HUTCHISON, M.D., F.R.C.P., Physician to the London Hospital; and DONALD HUNTER, M.D., F.R.C.P., Assistant Physician to the Hospital. London: Cassell and Co., Ltd. 1929. Pp. 684. 12*s.* 6*d.*

WITH the passing of Dr. Rainy the assistantship of Dr. Donald Hunter has been incorporated in the present edition of this well-known book. It is difficult to imagine how much the medical student owes to this work, for its use has been universal; and it is equally difficult to imagine the clinical clerk passing through the wards without at some time or another being seen carrying this compact little volume. This new edition possesses the same clear exposition and the same wealth of detail as its predecessors. Additions have been made, especially in the chapters dealing with the nervous system and pathological fluids, and in the section upon bacteriological investigations.

Although much of the older material has been replaced, we feel that still more can be erased.

A book that has functioned so well and for so long must deserve credit from reviewers. A few omissions may, however, be noted. An indication of the value of the radiographic examination of the lungs as an aid to diagnosis might have been included, especially since the X ray appearances of the heart have already found a place. Twelve pages of the chapter on the central nervous system are still devoted to the electrical stimulation of muscles and nerves, but no space is given to the important changes that occur in the cerebro-spinal fluid in spinal block. When dealing with the stomach and its position in the abdomen the authors say that "recourse is frequently had to inflation of the stomach with gas" in order to outline the borders correctly. This gives a wrong impression; it must be rare nowadays for such a method of ascertaining the size of the stomach to be used. Many of the diagrams are rather old fashioned; Fig. 87, representing actinomycosis in sputum, is not worthy of the book and would be better omitted.

These are but details; this work stands to-day, as for years past, a sure guide to the student in the complexities of clinical medicine, both before and after qualification.

MEDICAL GUIDES.

Interns Handbook: A Guide to Rational Drug Therapy, Clinical Procedures, and Diets. By Members of the Faculty of the College of Medicine, Syracuse University, under the direction of M. S. DOOLEY, A.B., M.D. London: J. B. Lippincott Company. 1929. Pp. 254. 12*s.* 6*d.*

THIS symposium is drawn up for the newly qualified hospital resident by the members of the Faculty of the College of Medicine of the Syracuse University to help him when he gropes "for that exact combination of the familiar facts of anatomy, physiology, chemistry, bacteriology, pathology, pharmacology, and exact clinical procedures needed in the emergency." The authors take a justifiable pride in having furnished precise details of treatment which the student has only learnt in general principle, but as resident has to apply promptly and with decision. The book is designed for a special period of the medical man's life, though, of course, its value for other circumstances is almost as great. The information given falls under two headings—that of drugs (including treatment of poisoning) and that of clinical procedures. Under the latter are sections on clinical laboratory work, serums, diets, and on each of the different specialties which have place in a general hospital. Written chiefly for an American hospital, this book contains the information which any freshly qualified practitioner needs to carry him through his new work.

Medical Guide for India and Index of Treatment. Third edition. By Lieut.-Colonel E. J. O'MEARA, F.R.C.S. Eng., I.M.S. (Ret.), late Civil Surgeon and Principal of the Medical School, Agra. London and India: Butterworth and Co., Ltd. 1929. Pp. 1138. 25*s.*

THE condition of the recently qualified student of medicine in regard to medical practice in England, and his feeling of ignorance of the practical points which count, must be lived again when the English doctor is met by the problems of Indian practice. Lieut.-Colonel O'Meara's book, which is now in its tenth year and has reached its third edition, is one which introduces the medical man to the intricacies of practice in India. It is a synopsis of medicine in all its aspects, but throughout with a special application. This bias is especially marked in the sections on preventive medicine and sanitation, on medico-legal work and lunacy, on hospitals and nursing homes, foods, and dietetics. These are the branches of medicine in which practice differs most in different parts of the world. As an instance of the thoroughness of the work, we note that in the section on rabies it is not only stated where treatment is available, but also what travelling facilities are granted for patients to reach the treatment centres. This book lightens the burden of all Indian practitioners, but most of all of the newcomers to that country.

TRAITEMENT DES AFFECTIONS NEURO-CUTANÉES.

By E. JUSTER, Assistant, St. Louis Hospital. Paris: Masson et Cie. Pp. 126. Fr.14.

THE growing recognition of the sympathetic and endocrine connexions and interactions of the cutaneous tissues certainly justifies an attempt to consider certain dermatoses from a new point of view, and has, doubtless, inspired the author of this short treatise. It must, however, be constantly borne in mind that the facts at our disposal are few, and that until the physiologists are in a stronger position to teach the functions of the sympathetic and endocrine systems, and their biological connexions, we must not allow assumption to carry us too far in the channels of ætiology and therapeutic endeavour. We may perhaps admit the claims of alopecia areata, vitiligo, and Raynaud's syndrome to be attributed to endocrine dysfunction, and we may perhaps suspect that lichen simplex chronicus, lichen planus, and sclerodermia will ultimately join this group, but we have no evidence that would entitle us to include—as is here done—such conditions as premature baldness, hypertrichosis, pemphigus, kraurosis vulvæ, and the Fox-Fordyce disease. Most English authorities would not agree with the views put forward on the ætiological importance of congenital syphilis. It is very rare to discover a positive Wassermann reaction in a case of Raynaud's syndrome, for instance, and yet the French favour a luetic factor in its production. The issue is evaded by emphasising the frequent absence of a positive reaction in cases of tabes and allied conditions, and asserting that "the custom of demanding a positive W.R. is the cause of many diagnostic errors." The argument can, of course, be used by both schools, but it is going too far to suggest that "the discovery of serological tests may be regarded as a catastrophe for many, and that the attitude of physicians who refuse to make use of them is readily comprehended." Considering that this book is designed for the use of practitioners and lays no claim to be a scientific treatise, such views seem to lack the merit of caution and might have been differently expressed. On the whole, however, the production is well worthy of perusal by all who are interested in the progress of dermatology, and whose knowledge is sufficient to prevent a too ready acceptance of hypothesis in the guise of fact.

TUBERKULOSE PROBLEMER.

By R. KJER-PETERSEN, M.D. Copenhagen: V. Thaning and Appel's Forlag. 1929. Pp. 125. Kr.3.50.

THE author of this book, who is in charge of the Tuberculosis Station in Copenhagen, is a refreshingly bellicose crusader who employs his knowledge of recent tuberculosis work in Germany and England to bring home to his compatriots the errors of their ways. With the reputation for having the lowest tuberculosis mortality in Europe, Denmark has come to be regarded as a "show child," as a stick wherewith to beat more backward countries. But even a "show child" sometimes wanders from the paths of rectitude. The object on which the author breaks his first lance is the statistical service, which has supplied the, in his opinion, misleading calculation that the average duration of the life of a consumptive, dating from his first symptom, is between seven and eight years. The author's own calculations, which deal only with sputum-positive cases, shows that 76 per cent. of such patients die within two years of the appearance of the first symptom. He compares the inclusion of all tuberculous patients in one class, without reference to the presence or absence of tubercle bacilli in the sputum, with the inclusion of all cases of albuminuria, orthostatic and the like, under the term nephritis. A whole chapter is devoted to sanocrysin. This drug, according to Dr. Kjer-Petersen, has not only been useless in some cases and harmful in others; it has also distracted attention in Denmark from the remarkable advances in tuberculosis made in Germany in the last few years. The author describes the campaign in favour of sanocrysin rather derisively as "smart business." The chapter on artificial pneumothorax deals largely with recent German work on this subject, and with the claim made in this country in favour of submitting some 50 per cent. of all cases of pulmonary tuberculosis to this treatment. As for village settlements in general, and Papworth in particular, the author's opinion thereon is best indicated by his choice of the three most important milestones in the history of the treatment of tuberculosis—Brehmer, Forlanini, and Varrier-Jones. It is probable that never before have the problems of tuberculosis—prevention, pathology, treatment, and social action—been thrown into the melting-pot as they have at the present time, and the author has done good service in stirring this pot and ladling out samples of its contents to his colleagues. One of the chief lessons of his book is that the most rapid and effective way to solve the many problems of tuberculosis is to follow closely what the other man is doing, even though he be a foreigner.

DIABETES.

The Diabetic Life: Its Control by Diet and Insulin. Fifth edition. By R. D. LAWRENCE, M.D., M.R.C.P.Lond., Chemical Pathologist and Lecturer in Chemical Pathology, King's College Hospital. London: J. and A. Churchill. 1930. Pp. 204. 8s. 6*d.*

A Handbook on Diabetes Mellitus and Its Modern Treatment. By J. P. BOSE, M.B., F.C.S. Lond. Calcutta: Thacker, Spink and Co. Pp. 192. 8s. 4*d.*

The Diabetic A.B.C.: A Practical Book for Patients and Nurses. By R. D. LAWRENCE. London: H. K. Lewis and Co., Ltd. 1929. Pp. 55. 3s. 6*d.*

Diabetics: A Manual for Patients Suffering from Diabetes Mellitus. By JOHN KNOWLES, M.R.C.S. Eng., L.R.C.P. Lond., D.P.H. Manch. London: Faber and Faber, Ltd., The Scientific Press. 1929. Pp. 87. 3s. 6*d.*

Practical Handbook for Diabetic Patients. By ABRAHAM RUDY, M.D. Boston: M. Barrows and Co. 1929. Pp. 180. $2.00.

A Book for Us Diabetics and Our Doctors. By DON H. DUFFIE, M.D. Published by Author, S. Lancaster, Mass., U.S.A. 1929. Pp. 120. $1.50.

FIVE editions of Dr. Lawrence's excellent manual, "The Diabetic Life," have been published in six years. The chief changes made in the present edition are in matters of detail, which are, however, of very great importance to the patient. Drs. McCance and Lawrence have now completed an analysis of the different foodstuffs which contain carbohydrate. They have shown that the amount of carbohydrate which can be utilised by patients is, in many vegetables and fruits, much less than was supposed. Thus a patient who ate 8 oz. of cabbage under the impression that he was eating 5 g. of carbohydrate was actually eating only about 2·5 g. It is more than probable that the old carbohydrate values have been responsible for attacks of hypoglycæmia, owing to the exchange of vegetables which were erroneously supposed to have the same carbohydrate value. The revised figures should be distributed to patients as soon as possible. Many new recipes are included, and will add considerably to the choice of puddings and savouries which can be made. As the equivalent amounts of carbohydrate, protein, and fat are always given, these delicacies can be varied without causing any change in the total value of the diet. The general advice to the patient is very good. In this edition the question of marriage is discussed. It is stated that it is not dangerous for men, but that the woman does run certain risks. There is also the added consideration that the child may develop diabetes. Dr. Lawrence makes the point that for the woman able to carry through a pregnancy satisfactorily great self-control and determination are required, and that she is at least as likely to transmit these valuable qualities as a taint of hereditary disease. The balance of opinion is that while marriage cannot justly be forbidden, pregnancy is inadvisable in all but the exceptional case.

Dr. J. P. Bose gives the results of his work as a research worker at the Calcutta School of Tropical Medicine and Hygiene. The chapters on the physiology of sugar regulation in the body are full, and contain some original work by Dr. Bose and Colonel Acton. They have provided the explanation of the puzzling report which reached us some years ago that insulin was destroyed in the hot climate of India. The error arose because the insulin was tested out on the native or Himalayan rabbit, which is now found to be very insensitive to insulin. A dose which will cause severe hypoglycæmia in the Belgian hare, which is commonly used in England for assaying the strength of insulin, has no effect on the Himalayan rabbit. The latter also differs in being much more sensitive to adrenalin than is the Belgian hare. The dietetic scheme has been drawn up for the three types of patient seen in India: (1) the European or Anglo-Indian; (2) the Indian who eats a mixed diet; and (3) the Indian who eats a purely vegetarian diet. The instructions for arranging the diet are quite clear. The diet tables which are essential for giving variety to the patient are unfortunately drawn up on the old system of so many grammes of carbohydrate per 100 grammes, and are therefore nothing like so easy for the patient to follow as the English 5 g. system. The indications for the use of insulin are good, and the instructions for its administration and for the gauging of the correct dose should be easily understood. The book will be of especial value to all workers who have to treat patients in India.

Dr. Lawrence has done a good service to patients with diabetes mellitus in writing a simple book, designed expressly for them and their nurses. His more technical book reviewed above, while it provides excellent matter for doctor and keen educated patients, has frightened many who desire only to understand the simple rules of diet and not to think too much about their disease. The statements about diabetes and the principles of its treatment are put in very simple form, and the rules given for the administration of insulin are good. It would be an advantage if the method of filling the syringe were described with diagrams, since many nurses do not know how to do this properly. The line ration is fully described, and the food tables on which this method is based are very valuable. The tables are drawn up on the basis that the weights of the different articles all contain 5 g. This method, which was first introduced by Dr. O. Leyton, and then greatly extended by Dr. G. A. Harrison, makes it very easy for the patient to vary his diet. In another edition Dr. Lawrence might consider giving the figures for the proteins in 7·5 gr. portions instead of 5 gr. portions, so as to correspond with the line ration scale. The recipes will be of the utmost value to patients who crave for more variety in their diet.

In a small manual Dr. Knowles has set out the elements of what a diabetic patient should know. Thirty-three pages are given up to food tables; here, as in Dr. Bose's book, the substitution of the 5 gramme method of calculating would be appreciated by patients. The instructions for insulin administration are clear. It is surprising that a syringe is recommended which is marked in minims or c.cm. instead of in units of insulin, as is now usual.

Dr. Frederick M. Allen states in the introduction to Dr. Abraham Rudy's book that "diabetes presents peculiar problems to certain elements of our population." Dr. Rudy has written this handbook in order to make the path easy for some of the immigrant races of America and for strict Jews who keep to the kosher regulations. The introductory remarks about the nature of carbohydrates, proteins, &c., are simple but adequate. The rules for insulin and the general management of its administration are good. The chief value of the book, however, lies in the diet tables and recipes. The latter number 180 in all, and are suitable for American, Jewish, French, German, Italian, and Armenian tastes than for British ones. The tables are given in two forms—so many grammes of carbohydrate in 100 grammes of foodstuff, and also as either 3 or 5 or 10 g. of carbohydrate in so many cups of foodstuff. Once the measure of a cupful is realised, this method should make it easy for any patient to follow the instructions given. The book lacks a general index, but has a complete index of recipes.

Dr. Duffie's book is written in a very breezy style, and is full of quaint expressions. More than half of it is intended for patients, and the clear directions are illustrated by numerous photographs; those of the method of preparing the syringe and giving the injection are very valuable. The recipes are good, but the diet tables here also are expressed in terms of grammes of carbohydrate, protein, and fat for 100 grammes, instead of on the 5 gramme principle now widely accepted in Great Britain.

AIDS TO ORTHOPÆDIC SURGERY.

By ERIC A. CROOK, M.Ch. Oxon., F.R.C.S. Eng., Assistant Surgeon, Charing Cross Hospital; Surgeon, Queen's Hospital for Children. London: Baillière, Tindall and Cox. Students' Aids Series. 1929. Pp. 232. 3*s*. 6*d*.

THE author of this little duodecimo disclaims any pretention to encroach on the province of the orthopædic specialist, and only aims, as he says in his preface, to meet the needs of the student of general surgery. As far as it is possible to achieve this end in the space allotted Mr. Crook has succeeded in doing so. The book will serve to whet the appetite of the reader, and lead him to consult the larger monographs on the subject. Still better, he may be stimulated to take an interest in one or more of the orthopædic clinics which are now scattered about the country, and to learn there something of the practice of the specialty. The technique of orthopædics, more perhaps than any branch of surgery, needs personal experience and practice.

A NEW TREATMENT OF TUBERCULOSIS.

By PIERRE HULLIGER, M.D. London: H. K. Lewis and Co., Ltd. 1930. Pp. 146. 8*s*. 6*d*.

IN this book the author claims to have found a specific for tuberculosis. The treatment consists of hypodermic injections of a substance containing salts of copper, silver, tin, and manganese, but since we are not told the exact formula we have only the assurance that the treatment is new. At the beginning of the book the author discusses various other methods of treatment, altitude, fresh air, sunlight, pneumothorax, and tuberculin, and he points out that none of these methods can be called a cure; with this part of the book we rejoice to find ourselves in agreement.

The arguments used in favour of Dr. Hulliger's treatment are most unconvincing. Several plates are produced showing patients before and after treatment. In one case the cure was said to be obtained in 13 days, but we are not informed whether the patient remained cured. Although we have yet no cure for tuberculosis, many of the methods of treatment adopted undoubtedly help to arrest the disease. We can find no evidence in this book that the treatment advocated therein is effective even in this respect.

FULL DENTURE PROCEDURE.

By VICTOR H. SEARS, D.D.S., Professor of Prosthetic Dentistry, New York University College of Dentistry. London: Macmillan and Co., Ltd. 1929. Pp. 135. 8*s*. 6*d*.

DENTURE prosthesis has undergone many changes during the last 20 years, usually in the direction of greater complication of procedure. There are at the present time several methods of denture construction to which the names of different dentists are attached, all involving a complicated series of stages. Each advocate of a particular method claims that his technique produces dentures which are natural, efficient, and stable. The fundamental principles of denture construction have, however, changed little in essentials during the last 40 years or more. It is doubtful whether the complex elaborations which have become increasingly popular have really added much to our ability to construct useful dentures, especially since they are mostly based on conceptions of jaw movements which are still hypothetical. There are certain cases, however, in which a special technique will prove useful and may enable the dentist to succeed where ordinary methods fail. This book is a practical manual in which the different stages of full denture prosthesis are clearly described in detail. We have no doubt that if the author's directions are carefully followed the results will be good. At first sight it may seem that the technique described is laborious and tedious. In practice, however, the various stages should not tax unduly the patience either of dentist or patient.

This book should prove a useful addition to the library of the up-to-date prosthetist.

DENTAL HISTOLOGY AND EMBRYOLOGY.

Second edition. By B. ORBAN, M.D., Professor of Dental Histology and Pathology, Chicago College of Dental Surgery, Loyola University. Philadelphia: P. Blakiston's Son and Co. Inc. 1929. Pp. 218. 16*s*. 6*d*.

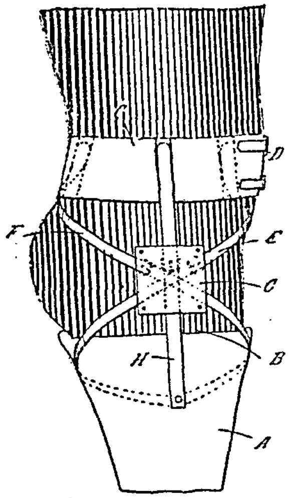
HITHERTO there has been no complete presentation in English of the work of the Vienna school of dental anatomy and pathology which has gained renown from the original work of Prof. B. Gottlieb in this field. Prof. Orban was a pupil of Gottlieb and is thus in a position to supply an authoritative account of his work on the development of the enamel cuticle and its relation to the eruption of the teeth and of the theory of the pathology of pyorrhœa which is based on this work. Many of the views held by Gottlieb and Orban are in conflict with those generally accepted, but the evidence here adduced is weighty and not lightly to be disregarded. The special value of the book is the large number of illustrations, chiefly photomicrographs, which are of unusual beauty. The text has been reduced to the minimum and is in the nature of a running comment on the illustrations rather than an illustrated treatise. Those familiar with the work of such microscopists as J. H. Mummery or Leon Williams know how clearly, in the hands of an expert, microphotographs can demonstrate the histology of the teeth. Prof. Orban's illustrations come up to the high standard set by these masters of the technique. No serious student of dental anatomy should ignore this book.

THE QUEEN'S HOSPITAL, SIDCUP.—The London County Council has decided to purchase this hospital for £20,000. The institution, which stands in 93 acres, is to be used as a convalescent home for patients from the hospitals that will be transferred to the Council on April 1st. A further expenditure of £7000 will be necessary to put the buildings in order, and the annual cost of maintenance, with 400 to 500 beds in average use, is estimated at £75,000.

New Inventions.

A BELT FOR THE ATTACHMENT OF ARTIFICIAL LIMBS.

In The Lancet of Nov. 10th, 1928 (p. 1008), there appeared under the title of An Improved Attachment for Artificial Limbs a short account of a body belt for this purpose, patented and introduced by Messrs. W. R. Grossmith. One of the difficulties which artificial limb makers have always had to contend with in cases of amputations of the thigh has been that of the method of attachment of the prosthesis to the patient's stump. This difficulty increases with the decrease of the length of the stump in more than an inverse ratio. It has been for years customary to attach the artificial limb to the body by means of suspenders passing over the shoulders. These might act satisfactorily in the erect position with the hip-joint extended, if carefully adjusted, but flexion of that joint and of the spine as in the sitting position threw the relationship between the parts and fittings concerned out of harmony, so that the socket of the artificial limb generally slipped forwards, or even—in the case of a very short stump—might slip off altogether. Moreover, the connexion between stump and socket was not a close enough one, and consequently allowed a good deal of play, or what mechanicians call "lost motion," with insecurity and inefficiency as a result. Various belts have been devised to meet this defect, and have been more or less successful, including, of course, the steel pelvic band and hip-joint, but the device referred to above seemed to me to be an improvement of promise and worthy of trial, and accordingly "security" belts were ordered for a number of cases by the Royal Surgical Aid Society. Enough time has now elapsed to enable some opinion to be formed as to the practical value of the belt, of which a diagram is reproduced herewith.



A. Thigh socket (or bucket) of artificial leg. *B*. Upper part of patient's stump. *C*. Waist-belt. *D*. Buckles of waist-belt. *E* and *F*. Leather straps. *G*. Guide over hip-joint. *H*. Additional strap, if required.

These patients have reported favourably, and those whom I have examined have a greater control of the prosthesis than they had formerly when wearing suspenders, and are less liable to falls. One patient whom I examined after some months' use of the belt said that she found herself able to check a stumble and recover herself in circumstances which with the old suspenders must have led to a nasty fall. Another case was one of an amputation leaving only 7 inches of stump, amputated 28 years ago, hitherto unable to walk without a noticeable outward swing. The wearer describes the benefits which she obtained from this attachment as: 1. In sitting in any public conveyance the leg does not slip at all, and keeps in a perfectly natural position without discomfort, either with both thighs parallel or with the two knees well apart. 2. In walking, the wearer is able to keep the leg as close as necessary to the sound limb and preserve a correct gait with an improvement in the contour of the hips. 3. She stated that a friend, seeing her for the first time since wearing the "security" belt, said, "It looks like you but it cannot be, as you are walking erect."

This attachment consists of a waist-belt furnished with a pair of straps, one of which is secured to the belt in front and the other to the rear of the belt, thence passing diagonally and crossing each other over the hip-joint, and finally passing around the thigh socket, and being there effectually secured to the inner side of the socket. These straps are adjustable for length, and, at the point of intersection at the hip, are arranged to pass freely through a guide. Further, where necessary, an additional strap is attached to the waist-belt at the outer side and carried straight down through the guide to the top of the socket of the artificial limb. It will be manifest that this arrangement of belt entirely obviates the necessity for any strap to pass directly downwards at the back of the wearer, securing much greater comfort in sitting. In addition to these advantages secured by this attachment, which can be fitted to practically every make of limb for thigh amputations, its very low cost is an important feature.

I may add that such a belt is peculiarly acceptable to female patients who find the use of suspenders very awkward, especially if they are inclined to embonpoint or have well-developed breasts.

E. Muirhead Little, F.R.C.S.Eng.,
Senior Surgeon to the Royal Surgical Aid Society, London, E.C.

Reports and Analytical Records.

ENERGEN BISMEAL NUTRIENT BREAKFAST FOOD.

(Energen Foods Co., Ltd., Energen Works, Willesden, London, N.W.10.)

It is claimed that 50 per cent. of this breakfast food consists of crushed whole wheat, from which nothing has been removed, the balance being made up of wheat gluten and milk proteins, the result being a "starch reduced" product suitable for a diabetic diet. On analysis the following results were obtained:—

	Per cent.		Per cent.
Moisture	10·0	Protein	35·0
Ash	1·2	Crude fibre ::	1·34
Fat	3·7	Carbohydrates ..	48·76

No trace of deleterious substances or preservatives was found. The calorie value of the food is 1714 per lb., and the composition of the food claimed by the makers is substantiated.

DEXTROSE ("CERELOSE").

(Corn Products Refining Co., New York, U.S.A., 17, Battery-place. London: Bush House, Aldwych, W.C.2.)

This sugar is a refined preparation of dextrose (glucose) made from corn (maize) starch. Chemical analysis shows it to be the pure hexose $C_6H_{12}O_6$ containing 7·6 per cent. of moisture, and having an optical rotation (calculated on the dry substance) of $[\alpha]_D + 53{\cdot}1$ at 68° F. Owing to its high degree of purity it is well suited for nutritional and other medical purposes.

North Middlesex Hospital.—This institution (950 beds) of the Edmonton Board of Guardians during the year ended on March 31st last admitted over 1000 patients more than in the previous year, the total, including births, being 9797; out-patients increased by more than 6000. Lieut.-Colonel Spencer Mort, the medical superintendent and director, reports that the accommodation is insufficient for ordinary requirements; in winter the pressure is severe. Increase of staff and further accommodation have, he says, become an urgent necessity. He adds that a special children's hospital for Middlesex is badly needed. At present children often occupy adult beds.

THE LANCET.

LONDON: SATURDAY, JANUARY 11, 1930.

LUNACY CERTIFICATION—FIRST AID FOR DOCTORS.

FURTHER and more leisurely study confirms previous estimates of the importance of the decision of the Court of Appeal in the case of Easton *v.* Johnson and Potts, discussed in THE LANCET of Dec. 28th, 1929, at p. 1371. By intervening at the outset to stay Mrs. EASTON's action against the two doctors who had certified her under the Lunacy Act, the Court relieved them of great anxiety and expense. Assailed by a claim for damages for negligent certification, a medical practitioner must fight to the end. It will make all the difference to him if the recent decision means that his preliminary right to ask the Court to stop the proceedings (under Section 330 (2) of the Lunacy Act) is really to furnish in future a substantial first line of defence. Has the law taken at last a turn more favourable to the medical profession? Will the House of Lords uphold the Court of Appeal?

An apparent change in the legal view deserves close attention. Under Section 330 (2), the Court is authorised to stay the plaintiff's proceedings against the certifying doctor if "satisfied that there is no reasonable ground for alleging want of good faith or reasonable care." In the Hume Spry case, Lord Justice BANKES seemed to hold that, in exercising this preliminary jurisdiction, the Court must not test the quality of the evidence; if there were any fragment of evidence in favour of the plaintiff, then—he seemed to infer—the Court must not at this stage weigh it against the possibly greater volume of evidence adduced by the defendant, but must simply decline to stop the case; if there were any scintilla of evidence to go before a jury in support of the claim, then the claim could not be withheld from the jury. Such a ruling, as Lord Justice GREER pointed out the other day, entirely nullifies the relief which Section 330 (2) was intended to give. There will always be some allegation on behalf of the plaintiff. "It is obvious," said Lord Justice GREER, "that any person bringing an action alleging that he has been improperly certified by the doctors, whether it be a man or a woman, will be able to put before the Court on affidavit some facts which, if proved, would support the action which has been commenced." It is highly probable, as the Lord Justice observed to Mrs. EASTON's counsel, that any plaintiff in this kind of action will say "I did not do any of the things they say I did; I did not have the delusions they say I had; I did not say to the doctors what they say I said; I am a perfectly sound man and I speak as such." That, said Lord Justice GREER, would be evidence of course that the certificate was given unreasonably; but if the existence of such evidence were to be allowed to bar the jurisdiction of the Court to make an order under Section 330 (2), it would be tantamount to repealing that enactment. "In my judgment the Court has to look at the whole of the evidence which has been put before it, and has, so far as it is possible, to weigh the evidence which has been given on affidavit, to come to a conclusion one way or the other as to whether there is reasonable ground for alleging want of good faith or want of reasonable care." Naturally the judges, especially those trained in the common law, dislike having to accept evidence in the form of affidavits; they would vastly prefer evidence which could be tested by cross-examination. But what else can they do? Parliament, as Lord Justice SCRUTTON observed, can hardly have intended that the Court, when exercising this jurisdiction under Section 330 (2), should hear all the witnesses examined and cross-examined; this would lead to almost as great expense as the full trial of the action. Parliament clearly contemplated that the Court, dealing with applications under Section 330 (2) to stay the plaintiff's proceedings, must work by means of something less than the full examination and cross-examination of witnesses; and so, though the Lord Justice added that he himself had very little faith in affidavits as a means of eliciting the truth, the Court must expect to have to weigh affidavits from the one side against affidavits from the other. Mere contradictory affidavits, said Lord Justice SCRUTTON, are of very little use to the judge in deciding whether he can stay the action. "If A, B, C, D, and E say one thing, and F, G, H, I, J, and K contradict them, that is not a case in which the Court can act, unless, indeed, A, B, C, D, and E have made such obviously ridiculous statements that it was clear that nobody would pay any attention to what they said; you must have such a state of things, in my view, that the Court is satisfied that no reasonable jury could on that evidence find that there was want of good faith or of reasonable care."

In Mrs. EASTON's case there was ample evidence from independent witnesses both to prove her delusions and to establish the fact that the certifying doctors had made a prolonged, and not a cursory, examination of her. The affidavits by medical witnesses in support of the two defendant doctors were authoritative and valuable. On the other hand, there were affidavits by two personal friends of the plaintiff, adduced on her behalf. These carried the less weight in that one of the friends had not seen her between May, 1926, and April, 1928, and the other had not seen her between 1918 and 1928. The latter in her affidavit suggested that it would have been sufficient to have placed Mrs. EASTON in a nursing home, but, as Lord Justice GREER said, "You cannot get certificates from doctors to make people go into a nursing home; if people do not want to go, they do not go." Possibly it was the plaintiff's own affidavit which was most damaging to her case, because the Lords Justices were able to find admissions in it which reconciled them to the absence of cross-examination. Mrs. EASTON's affidavit purported to be a reply to the affidavits filed by the medical and other witnesses recounting her delusions. Her affidavit gave so qualified a denial to some of the statements attributed to her that it went some way to confirm the truth of the affidavits on the other side. Moreover, her affidavit did not deal at all with some of the acts and speeches which had been cited as evidence of her insanity; her counsel seems to have conceded that by this omission she must be taken to have admitted the truth of them. Master JELF and Mr. Justice FINLAY (whose decision not to stop the case the Court of Appeal over-ruled) were mainly concerned, we know, with an affidavit by Dr. RISIEN RUSSELL. Mr. Justice FINLAY hinted that he thought Mrs. EASTON's action had no prospect of success, but he felt that Dr. RUSSELL's affidavit constituted some evidence which a jury might deem to be in her favour. The history of this affidavit seems to have been as follows. Counsel for the defendant doctors, when applying under Section 330 (2) to Master JELF, apparently quoted Dr. RUSSELL's affidavit in the

Hume Spry case to the effect *that it was not* essential to have a physical examination of the person to be certified. The Master then asked that Dr. Russell should make an affidavit as to the necessity of a physical examination in Mrs. Easton's case. Dr. Russell thus came to assert the series of physical examinations which he said should have been made. The pupil of the eye should have been examined—an ophthalmoscope employed to detect pressure on the brain—search made for tremor of the face, tongue, and hands—knee-jerks tested, and so on. What the Court of Appeal thought of these assertions we know. Lord Justice Greer said that, if it were literally true that there must be no certification without physical examination, then, even when an alleged lunatic came into a room with an open knife and attacked the two doctors and afterwards tried to kill himself, it would still be necessary, according to Dr. Russell, that they should test his physical jerks before certifying him. Lord Justice Scrutton, as reported in our columns a fortnight ago, said that a doctor who comes to examine an alleged lunatic is not employed by the patient and has no authority to apply all these tests to which the patient would probably object strenuously. He mentioned the case (which he had once tried at Exeter) of a lunatic who believed himself to be a member of the Royal Family, with special rights of punishing anybody with whom he disagreed. If the patient expressed such delusions, a careful doctor (provided that he were satisfied that the patient was not playing him a joke) would be entitled to deem him of unsound mind without further examination.

The upshot of the Court of Appeal's decision is to furnish valuable first aid towards the relief of a certifying doctor from legal liability. But everything will depend upon the evidence which the doctor will be able to produce on an application under Section 330 (2), when he asks the Court to stop the plaintiff's action. He should put himself in a position to prove, for example, so small a matter as the length of his examination; by noting down the time taken he may be able afterwards to refute the usual allegation by the patient that the examination was casual and perfunctory and that "he only looked at me for a couple of minutes." And the doctor should bear in mind the value of corroboration. All this precaution adds new worries to the never very welcome duty of certifying. But it may save trouble in the end with the law as it is.

◆

AN EAST AFRICAN MEDICAL RESEARCH FUND.

In the 200,000 square miles over which are scattered the native reserves of Kenya there live 2,500,000 Africans, poor, illiterate, destitute even of such household furniture as a bed, and usually without clothing. Not less than 1,000,000 of them are constantly suffering from malaria, and probably not more than a score are within reach of a medical man. Their malarial index is, in places, as high as 80 per cent., and certain of them pass from their reserves to work on farms, roads, railways, and in towns, where they generously spread their infection to European and Asiatic non-immune immigrants. These Africans formed the core of the problem which confronted Colonel S. P. James, the advisor on Tropical Diseases to the Ministry of Health, when he was deputed to tour East Africa and report on the malaria position there, and the measures which could be taken to mitigate it. First of all, as he points out in a report now published,[1] he had to determine where a beginning should be made. Was the economic state of these people to be bettered, so that their health should be improved, or was the attack to be begun in the other direction? He makes clear once again that there is no royal road to malaria control, but that the best means of effecting this must be discovered afresh for all localities, for they vary with different conditions of climate and population. In the great area under discussion the measures needful for a direct attack on the malaria parasites in man and anopheles would be difficult and expensive, and their application would be beyond all available resources. Merely to envisage the task of screening the rough shelters of these people, of inducing the general use of mosquito nets, mosquito boots and quinine, and of applying anti-larval measures generally, is to be convinced of its futility. Economic progress must be made, and the native must be educated to realise the advantages he can get from the applications of medicine and hygiene before any real beginning can be made in the effort to stamp out malaria from the native reserves, and thus to eliminate a reservoir from which malaria is being widely diffused through Kenya.[2] This will be a long process, and no dramatic results can be looked for to cheer those who spend their lives in propaganda which will take generations to soak in.

Fortunately an indirect attack—or, in other words, the application of well-tried measures directed to protect from malaria farms, railways, roads, and towns—is feasible and promising, but here again Colonel James insists that there is no short cut: even now much investigation in field and laboratory is needed before local antimalarial work can be used to the greatest advantage. The small technical staff required for this work, who might receive part of their training in India, includes a medical entomologist and an antimalarial engineer; this team should, it is advised, continue and extend the work initiated by Colonel James—work which implicated *Anopheles funestus* and *A. costalis* as two of the local carriers; and should keep in touch with the world's malaria literature and with the technical experts of all the Government's departments, whose activities may influence malarial incidence. Sound measures are advised to meet the special needs of certain sections of the community, but Colonel James refuses to minimise the considerable difficulties involved. For instance, Colonel James found that while in Uganda and parts of Rhodesia everyone who could afford it had a screened house, in Kenya hardly anyone seemed prepared to pay for this protection; and he cites a case where, in spite of nine attacks of blackwater fever between them, a farmer and his wife had been content to live for sixteen years in the same necessarily unscreened wattle and daub house. Not that screening can be firmly trusted; inside all the screened houses of Government officials with whom he stayed Colonel James caught mosquitoes, and it is specially significant that medical officers living in these same screened houses saw to it that they and their families wore mosquito boots after dark, and slept under curtains. Since then, whether from faulty workmanship or from the carelessness or laziness of servants, screened houses are not in practice mosquito-proof, it is only by incessant watchfulness that even Europeans can escape malaria until such time as steady, sanitary education of all races has done its slow work. Regarding towns, Colonel JAMES writes "no anti-malarial scheme, based on measures to reduce mosquitoes has ever been successful which did not include legislation to enforce the necessary measures." Research and education working hand in hand hold promise for the future, but discipline must also play a part.

---

[1] Report on a visit to Kenya and Uganda to advise on antimalarial measures. By S. P. James, I.M.S. (retd.), Advisor on Tropical Diseases to the Ministry of Health. Published by the Crown Agents for the Colonies, 4, Millbank, London, S.W. 1s.

[2] A Government report on the public health of Kenya for 1928 has just been published, and is reviewed on p. 113 of this issue. It provides some pertinent intelligence as to the malarial position existing during the year.

For the furtherance of research the pattern advised is the Indian Research Fund Association, with its record of valuable work, its annual Government contribution of £33,000, and the aid given to it by donors from the general public, who thereby obtain the privilege of suggesting lines of investigation. The report advises the initiation of an "East African Medical Research Fund," with a yearly grant of £5000 from each of the Governments of Kenya, Uganda, and Tanganyika. The aggregate amount would suffice to maintain workers set apart for the sole study of malaria, and would thus provide for that intensive scientific campaign for which the PRINCE OF WALES asked so earnestly in a speech delivered in Nairobi on Armistice Day, 1928. This speech made a profound impression in East Africa, and was clearly responsible for initiating the investigation from which Colonel JAMES's admirable report has emerged. Some local disappointment may be caused that no more concrete suggestions could be made. The lay public wearies of exhortations to spend money on research, when it would welcome a demand for a greater sum for a well-defined, simple scheme of engineering. But Colonel JAMES has spoken bravely and honestly, and no one who knows anything of endemic diseases will disagree that while our tropical lands can exchange experiences with advantage, each one has to work out for itself, in its own place, its own malarial problem.

◆

DEPRESSION.

THE comparison between DARWIN and FREUD has recently been drawn afresh. In many respects the troubles of psychiatrists to-day do indeed resemble those of zoologists when DARWIN had convinced them that their systematic zoology must be reconciled with the process of evolution. Great geniuses like KRAEPELIN had studied the end-products and described outstanding groups of mental symptoms, cutting, so to speak, transverse sections of mental disorder. Then came FREUD, insisting, as Sir FARQUHAR BUZZARD pointed out in the Purvis Oration which we published last week, on a longitudinal section, wherein the evolution of these disorders could be traced from earliest childhood and before. This inevitably meant some confusion; apparently related species were found to have very different origins, while offspring of one kind of psychological trauma might diverge to produce very different-looking diseases. Systematic psychiatrists are still struggling with the reorganisation of their classification, and the general practitioner may well feel helpless and bewildered when he is called upon to deal, practically and promptly, with the end-products. Suitable treatment for one kind of mental disorder may be the worst thing in the world for another kind which closely resembles it, and two apparently similar cases call for widely differing prognoses.

Commonest of all symptomatic groups is that which may be vaguely called "depression." Hardly a day passes but the practitioner meets a patient who complains of lack of enthusiasm and vitality. The doctor has to decide, perhaps quite promptly, whether the case calls for a tonic, a digestive, a search for focal sepsis, a cheery reassurance, a pathological examination, a psychological analysis, a rest, or a certificate under the Lunacy Acts. He has also to struggle against the almost overwhelming temptation to make a meaningless diagnosis of "a bit liverish" or, as Sir FARQUHAR BUZZARD suggests, "neurasthenia"—a diagnosis which will very likely satisfy the patient but can never satisfy the professional conscience. He owes a real debt of gratitude to those leaders who, like Sir FARQUHAR, try to differentiate for him the different types of mental case in language free from technicalities. From the "dump" of neurasthenia Sir FARQUHAR draws out two distinct groups, the anxiety state and the manic-depressive state. Some of his readers may be troubled by a suspicion that the problem is not quite so simple as they are here led to believe, but most will be more than grateful for guidance in the distinction of types of depression which require fundamentally different treatment. An important fact not taught in the medical schools until quite recent times is that there are far more manic-depressives outside than inside mental hospitals. It may not be wise to admit to the patient that his depression, though it may have been precipitated by some external cause, is really only the reverse picture of his own buoyant self-confidence and that in time the cycle will be re-established. But it can do no harm to dissuade his friends from attempts to brace and activate a mind whose depression increases after effort and whose chief symptom may be an abnormal fatiguability. A practitioner who has grasped the distinction insisted on by Sir FARQUHAR has at least his mind open to the study of one of the commonest and most distressing maladies he will meet, and has put himself in a position to help both the patient and his friends.

Dr. R. D. GILLESPIE from his experience at the Cassel Hospital has also been trying to differentiate various types of depression,[1] and distinguishes three classes: the reactive, the autonomous, and the involutional. In the first group he puts those who are susceptible to environmental influences, both internal and external, and whose illness seems to have been precipitated by some obvious external cause, such as sickness, bereavement, or business difficulties. The autonomous group is a mixed one, including depressions which appear as part of the splitting-up of a personality (schizophrenic), those which are part of the direct development of a personality, and those which appear as a phase in a mood-cycle (manic-depressive). In this last group the condition varies little if at all in response to intercurrent stimuli, and a tendency to self-accusation is much more often found here than in the reactive group, whose victims generally blame their environment. Dr. GILLESPIE thinks that the presence or absence of reactivity is likely to be the most useful sign in indicating prognosis and treatment, although he admits that no one sign can ever be a touchstone. The prognosis is much better for the reactive than for the autonomous, and only the reactive are at all accessible to psychotherapy. Another effort in the same direction is that of Dr. MARJORIE FRANKLIN[2] who distinguishes psychoses, psychoneuroses, and character-formations. She approaches them from the evolutionary point of view and characterises the psychoses as those conditions in which the fixation is at a low—first and second oral or first anal—stage, the object relationship auto-erotic or narcissistic, destructive impulses strong and ego changes predominant. In other words, the psychotic ego is so changed that it will tolerate uncritically or fail to recognise as arising from itself the repressed impulses and phantasies. In the psychoneurotic states the fixation is on a higher level—second anal, phallic, or genital—the destructive impulses and narcissism less marked and the changes predominant—i.e., the repressed material returns in a distorted form which is acceptable to the ego. In character-formations the trouble is more diffuse, resembling a toxæmia rather than an abscess; the patient is in much closer contact with reality and tends to work off his conflicts by outward behaviour. Dr. **Franklin** refrains from emphasising diagnostic points, admitting that diagnosis must be based on a clinical sense and an observation of what is, rather than a tracing of how it arose.

---

[1] Guy's Hospital Reports, 1929, lxxix., 306.
[2] Journal of Mental Science 1929, lxxv., 671.

The practitioner is not always able to learn much from these careful studies. Dr. **Franklin** speaks in a tongue so specialised, as is necessary, that few can profit from her guidance. Dr. **Gillespie's** differentiation of depressive states is not easily followed by those unfamiliar with the language of modern psychiatry. These two workers and many others are recording their experiences for the expert to interpret and criticise. Doubtless they hold that the time for simplification is not yet. It is true that a great deal more patient and laborious investigation is necessary before the practitioner can expect any handy diagnostic chart to help him in differentiating his depressed patients. Only those who have had long and intensive experience of mental disorders can make reliable diagnoses and indicate the best treatment, and even they are liable to a wide margin of error. Sir **Farquhar Buzzard** is not addressing experts. He speaks to those whose training in psychical disorders has been far outstripped by their training in physical ones. His teaching is the more valuable because it comes from one who is known to be a physician with a special bias towards organic neurology. If the practitioner will adopt as a preliminary working rule the simple distinction he draws, the unfortunates whose mental state is not amenable to brisk encouragement and arises from no preventable or curable lack of adjustment to environment will be saved from the whip that jocular friends can wield. The anxious, on the other hand, will not be left to brood in solitude but will be helped to believe in their own fitness to shoulder their burdens.

Fellowship of Medicine and Post-Graduate Medical Association.—An all-day special course in Diseases of Children will be held at the Queen's Hospital from Jan. 13th to 25th. This hospital specialises in teaching by demonstration rather than by lecture. From Jan. 27th to Feb. 8th an intensive course in medicine, surgery, and the specialties will be held at the North-East London Post-Graduate College (Prince of Wales's Hospital, Tottenham, N.) from 10.30 A.M. to 5.30 P.M. daily. Members of the Fellowship not taking the whole course are invited to the formal clinical lectures at 4.30 P.M. On Jan. 21st the Fellowship will start a new series of lectures at the Medical Society of London's lecture room. The lectures will be given at 4 P.M. on Tuesdays and are free to members of the medical profession. (It is to be noted that their day and hour has been altered.) Detailed syllabuses of these courses and lectures may be had on application, as also of the new series of clinical demonstrations in medicine and surgery, beginning on Jan. 23rd, at various London hospitals. Besides the special courses arranged for 1930 the Fellowship arranges a general course consisting of the clinical practice of its associated hospitals. Ticket-holders are provided with a programme which sets out the names of the clinics under subject headings, leaving them free to make out a time-table in accordance with their requirements. Tickets are issued for periods ranging from a week to a year. Arrangements can also be made for part-time work.

Annotations.

"Ne quid nimis."

NATIONAL HEALTH INSURANCE: TWO POINTS OF VIEW.

The French Academy of Medicine, at their séance on Dec. 3rd last, received two important communications on national health insurance which are of special interest at the present time in view of the recent legislation making health insurance compulsory throughout France. The first, that of M. Paul Strauss, "Les bienfaits des Assurances sociales pour la Santé publique," placed compulsory insurance in a very favourable light, while in the second, that of M. Weiss, Dean of the Strasburg Medical School, "Les dangers de l'Assurance contre la Maladie," a strongly opposed view was taken. The two communications and the discussion that followed make interesting reading for those who are concerned with health insurance in this country.

M. Strauss contended that during the many years that the system of compulsory health insurance had been working in Germany (and Alsace-Lorraine) the criticisms directed against it had dealt with details only, and that the beneficial effect of the system on the public health had never been questioned by any well-informed *hygiéniste*. The attack of Dr. Liek, whose book has recently been translated into French by M. Weiss under the title "Les méfaits des Assurances Sociales et les moyens d'y remédier," and that of Prof. Eppinger, which was communicated to the Academy on Oct. 22nd by MM. Merklen and Wolff, can be regarded as of individual character, representing nothing more than isolated opinions. Against them he placed the fact that 85 per cent. of the doctors in Germany were in the service of the insurance societies (*Krankenkassen*), and that the organised body of the German medical profession, at their congress at Essen in June, 1929, while contending that insurance administration should be amended—particularly by the general recognition of the principle of free choice of doctor and the removal of restrictions on entrance into insurance practice—had nevertheless recorded their view that the insurance system is indispensable to the German people. M. Strauss referred to the three monumental studies of national health insurance published in 1928 by the International Labour Office, and claimed that these documents showed that the German insurance societies had developed into potent agencies for the promotion of public health. At first chiefly concerned with administering cash benefits, they were now providing general practitioner, specialist and hospital treatment on an extensive scale, not only for the insured population but also for their dependents, and were to a rapidly increasing extent developing measures of prevention. He contended that the improvements in public health in Germany that had been secured during recent years were largely due to these organisations, and he gave statistics which he thought told strongly in favour of this view.

M. Strauss was followed by M. Weiss, who took up a contrary position. He also had recourse to statistics, and quoted figures which, he held, showed that in certain important matters—e.g., the prevention of infant mortality and of tuberculosis—Germany with her insurance system had lately fallen behind France and the United States, where (apart from Alsace-Lorraine) there was as yet no compulsory insurance actually in operation. He thought, however, that the value of a national insurance system could not be estimated by statistics, but only by a close study on the spot of the actual working of the system, and of its influence on the patients, the medical profession, and the public health. For years he had studied the system in Alsace, and he had been compelled by the facts to take the view that its influence on all three had been harmful. The vast sums expended by the insurance societies would, he said, have been far better employed in developing the services of public hygiene, in which lay the surest hope of health progress. The treatment given to insured patients was, he found, often open to criticism, partly owing to the interference of the insurance societies with the discretion of the doctors, of which he gave examples. What, however, gave him most concern was, as he considered it, the degrading effect of the insurance system on the morale and efficiency of the medical profession. It began among the students, who, knowing that insurance practice will be open to them after qualification, hasten to obtain their diplomas with the minimum of study instead of taking the fullest advantage of the facilities offered them to equip themselves with the skill and knowledge by which alone they can become worthy of their vocation. Entered upon insurance practice, the doctor was under great temptation to scamp his work, and in particular to yield to the importunities of patients to issue certificates of incapacity without sufficient justification. The medical profession was being divided into two classes—private practitioners and the doctors in the employ of the insurance societies, and its prestige had been seriously lowered in public estimation. He viewed the effect of the insurance system on the medical profession with grave concern.

It would seem that M. Strauss has painted too bright and M. Weiss too dark a picture. On the one hand, it can hardly be doubted that the past conflicts between the German *Krankenkassen* and the doctors have not enhanced the credit or the efficiency of the German insurance system, and there are those who hold that the activities of the *Krankenkassen* have encroached upon the field of the public health authorities, with consequent overlapping and waste of effort—shortly, that the work of the two sets of organisations stands much in need of coördination. On the other hand, it is difficult to accept the pessimistic view taken by M. Weiss. In every profession there are individuals who fail to reach a proper standard of professional conduct, and the instances given by M. Weiss seem to afford an insufficient basis for his general indictment of the insurance system. It is curious that on neither side was any reference made to the British system of national health insurance, in the administration of which, especially in the disciplinary procedure, the medical profession takes a prominent part. The amendments of insurance administration for which the German doctors have long been contending have for the most part been embodied in the British system since its inception, and M. Weiss and those of his colleagues who share his forebodings might with advantage devote some attention to the conditions under which insurance practitioners are working in this country.

THE DICK TEST IN MANCHURIA.

IN another column we publish an abridged account of recent observations on scarlet fever carried out at the Japanese Isolation Hospital, Dairen, by Dr. T. Toyoda and his colleagues. This work will not fail to attract interest in this country, since most of the difficulties which have been met with by British workers are recorded and discussed. For example, from general principles and from analogy with the Schick test it would be expected that all patients in the initial stages of scarlet fever should be Dick-positive. In the early history of the Dick test it was at one time thought that all patients in the later stages of convalescence should be Dick-negative, but in recent work this has not been observed in any large series of cases even where great care has been taken in adjusting the Dick dose. In a series of tests recorded by C. C. Okell and H. J. Parish,[1] 18 per cent. of late convalescents were Dick-positive and 65 per cent. of medical students with a convincing past history of scarlet fever were Dick-positive; though, if the incidence of relapses and second attacks is considered, it is almost certain that the majority of these Dick-positive persons were not susceptible to the disease. Toyoda and his colleagues found 15 per cent. of convalescent patients and 25·4 per cent. of persons with a past history of scarlet fever to be Dick-positive.

In order to explain these and other difficulties K. Ando,[2] also working in Dairen, has made a careful study of the constitution of Dick toxin. He believes that he can separate the toxin into a heat-labile and a heat-stable constituent. The former appears to have the properties of scarlet fever toxin proper, the latter to have certain allergic properties which are held to account for the majority of difficulties met with in interpretating the Dick test. What the relationship is of these two fractions to the nucleoprotein and the carbohydrate substance described by O. T. Avery and M. Heidelberger, H. Zinsser and his associates, and R. C. Lancefield in connexion with the cell constitution of bacteria, further investigations will no doubt show. Toyoda and his colleagues have found that individuals with a positive Dick test may have enough antitoxin in their serum to blanch a scarlet fever rash when used in the Schultz-Charlton test. They find that such individuals are sensitive to the heat-stable but not the heat-labile constituent. They comment on the known difficulties of obtaining complete neutralisation when mixtures of Dick toxin and antitoxin are injected into certain people. When the heat-labile constituent alone was used the number of Dick-positive patients in late convalescence was materially reduced. Pseudo-reactions are ascribed to the heat-stable constituent; they are, however, so rare with the toxin preparation used in this country that it is doubtful if the explanation of Ando and Toyoda can be held to account for the difficulties of interpretation which are met with by workers with the Dick test here and elsewhere.

The Japanese workers have brought forward a carefully documented report which confirms in general the experience of most modern workers on scarlet fever. They consider the hæmolytic streptococcus to be the sole ætiological agent in scarlet fever, that the Dick test is a valuable guide to susceptibility even in its present form, and that antitoxin is of great value in the treatment of the disease. By their analysis of the active constituents of Dick toxin they have opened up a field of inquiry which can hardly fail to arouse general interest and which may possibly lead to considerable practical improvements in the Dick test.

INTERNAL DERANGEMENTS OF THE KNEE-JOINT.

IN a report[3] presented to the annual congress of the Swiss Surgical Society Dr. Raoul Hoffmann, of Geneva, discusses the relation between injuries of the semilunar fibro-cartilages and arthritis deformans. His figures are drawn from the records of the Swiss assurance institutions, and the value of the provisional conclusions is much reduced because the patients were insured and were not in a hurry to get well, and because the operations were done by surgeons of very diverse technique. Moreover, he is unable to say from the available statistics what is the relative frequency of arthritis deformans in knees operated upon, as compared with those treated without operation. His personal experience suggests that other lesions associated with rupture of a meniscus play an important part in producing arthritis. The second and by far the greater part of his report, however, deals with the surgery of menisci in England. This, he says, is remarkable—for its quality doubtless, but still more for quantity—since individual operators have two or three thousand arthrotomies for meniscal lesions to their credit. The English technique is long-established, so that specialists have scarcely changed it during thirty years; yet statistical studies are scarce, possibly because the operation has become so firmly grounded as to need no more discussion. Dr. Hoffmann made a special visit to this "Holy Land of internal derangement of the knees" last spring when he spent a fortnight interviewing surgeons and studying their work in London and Newcastle-on-Tyne and, doubtless, Liverpool. His conclusions, which are obviously intended for Swiss and not for British readers, are sufficiently complimentary to our surgical self-respect, but it is unnecessary to follow him into details which will largely be familiar. His researches at home and abroad lead him to say that arthritis deformans cannot be always avoided after operation; that the more perfect the operation the less is the risk; that complications such as foreign bodies (implying previous inflammation) greatly worsen the prognosis; and that the patient's susceptibility is an important factor. He is disposed to lay stress on the views of Leriche, who holds that trauma unfavourably affects the sympathetic innervation of a joint and that through the action of this system arthritis may supervene even when an operation has been conducted with perfect technique and for an uncomplicated cartilage lesion. Finally, Dr. Hoffmann concludes that meniscotomy, notwithstanding its present imperfections, is justifiable and often necessary, for in the great majority of cases its benefits much outweigh its drawbacks. This is a conclusion which many surgeons in this country will consider almost pessimistic. In the absence of knowledge of the frequency of arthritis deformans in knees whose semilunar cartilages have not suffered known injury, and on which no operations have been performed, it seems impossible to decide in any given case whether arthritis when it supervenes on meniscotomy is or is not caused by the surgeon's intervention.

EFFECT OF LIVER ON NERVOUS LESIONS OF PERNICIOUS ANÆMIA.

WHEN liver diet was introduced for pernicious anæmia it was hoped that the nervous manifestations of the disease would respond to the treatment. Exactly how far they do so is still doubtful, for the reports are somewhat contradictory. C. C. Ungley and M. M. Suzman[1] have investigated the histories of 61 patients showing nervous symptoms; 30 of them had received a diet containing large amounts of liver while the other 31 had not. In the first group 17 had improved and 5 had died, whilst in the second group none had improved and 28 had died. These writers think that the benefit was due rather to some specific effect of the liver than to mere improvement in the blood count and general condition; they suggest that pernicious anæmia is probably a deficiency disease in which constitution plays a large part.

But the good results they record are not consistent with the usual experience. Thus Hans Curschmann[2] goes so far as to say that he has not yet seen a single case of pernicious anæmia in which the spinal symptoms were definitely improved by liver. Many, indeed, had actually deteriorated under this treatment, and Curschmann lays stress on its ineffectiveness even in those cases in which the blood changes are but slight. It is clear, he says, that the nervous lesions may actually get worse after the blood picture has returned to normal and the condition has otherwise improved. In a review of the subject which was published not long ago in our own columns[3] Dr. Douglas McAlpine noted this same fact and pointed out that it is the spastic type of degeneration which most particularly progresses in spite of treatment. Of his 11 cases only four made slight improvement whilst four became definitely worse. He observed some benefit upon mild mental symptoms from the action of liver diet and some lessening of paræsthesias but found no appreciable change in the reflexes. He concluded that the effects of liver treatment upon the nervous symptoms are variable, and that it does not directly combat the neurotoxin which is at work. Curschmann also supports the original theory of Minnich that the myelitis and the anæmia are brought about by a common toxin which in one case affects especially the blood, in another the spinal cord, and in a third the two together. Thus the cord symptoms may be present even before any detectable evidence of anæmia is present—a fact which bears against the theory that the anæmia itself leads to a nutritional disorder of the spinal cord. Moreover, the severest forms of secondary anæmia are only very rarely associated with nervous complications, whereas they are a common accompaniment of pernicious anæmia. And the patients in whom mental changes were noted by McAlpine had none of them a red cell count below 3,500,000. Ungley and Suzman, however, consider that with improvement in the blood picture the cord changes may so regress as to show that they are not necessarily permanent.

There can be no doubt of the persistence of achylia gastrica under liver treatment, and it certainly seems as though liver therapy was largely symptomatic and not directed towards the actual cause in this disease. In THE LANCET of Jan. 4th (p. 22) Dr. A. C. Hampson reported a case which seems to be entirely refractory to liver treatment and some observers think that the number of more or less refractory cases is increasing. On the other hand, many patients have been able to omit the diet without any apparent relapses. Further research will probably prove that something more than a simple dietetic deficiency is at the root of the complex syndrome of glossitis-achylia-pernicious anæmia-degeneration of the spinal cord. Truly radical therapy is likely to take the form of eradication of some provocative toxin—perhaps from focal sepsis—rather than the removal for symptoms by the use of liver.

OBSTRUCTION OF THE CENTRAL ARTERY OF THE RETINA.

CASES of sudden blindness in one eye are far less common than the histories given by patients would lead one to suppose. One of the most frequent causes of such a symptom is the sudden stopping of the vascular supply of the retina. The ophthalmoscopic picture is characteristic when the patient is seen within the first few weeks after the onset of blindness. Besides the noticeable diminution of the size of the blood stream in the retinal arteries, and the almost complete cessation of the circulation (shown by the impossibility of producing pulsation by pressure), there is an unmistakeable cherry-red spot at the macula, due to œdema of the surrounding retina. Following von Graefe, who first made the diagnosis in 1859, the older text-books always speak of the condition as "embolism of the central artery of the retina." For many years it has been well recognised that not all these cases are due to embolism. Primary thrombosis has been suggested as the cause in cases where there were prodromal attacks of temporary obscuration of vision. For the last 30 years or so much stress has been laid on disease of the inner coat of the artery—"endarteritis obliterans"—as a possible cause of the obstruction, according to some authorities by far the most usual cause. The possibility that muscular spasm of the arterial wall occurs and lasts long enough to cause death of the ganglion cells supplied by the artery must also be considered. Many cases have been recorded in which actual contraction and subsequent relaxation of the retinal arteries have been observed with the aid of the ophthalmoscope, and it must be remembered that spasm, besides being a primary cause, might be secondary to an embolus or thrombus. In the November number of the *British Journal of Ophthalmology* H. V. Coverdale publishes a study of 11 cases of obstruction which came under his notice last year when he was house surgeon at Moorfields. Eight of these patients had valvular disease of the heart, a circumstance that points to embolism as the cause of their eye lesion. In one case there was definite proof of embolism, so far as ophthalmoscopic examination can prove anything, for an obstructive white mass seen at the bifurcation of the artery on the disc was definitely observed to move on into a peripheral artery as the result of vigorous massage and the administration of nitrite of amyl, given within three hours of the onset of blindness. Pathological proof of the occurrence of this phenomenon has been afforded in rare cases where the patient has died within a few days of the onset of blindness, and the eye was examined before secondary changes made impossible any distinction between embolism and thrombosis.[1] The proof that embolism is at any rate one cause of the condition may be considered complete. As much may be said for endarteritis, when the inner coat of the artery gradually becomes thickened till the blood stream becomes so tenuous that a slight diminution in the pressure from behind is sufficient to stop the stream altogether. In these cases and in those due to primary spasm prodromal attacks generally precede the onset of blindness.

[3] THE LANCET, 1929, ii., 643.

A further matter discussed in Mr. Coverdale's paper is the reason why the stoppage of the circulation in these cases is seldom absolutely complete. In some cases the papillo-macular triangle is supplied either by an obvious cilio-retinal artery or by one arising from the central artery on the proximal side of the spot occupied by the plug. Apart from these cases there is evidence that a certain amount of capillary anastomosis occurs between the capillaries in the immediate neighbourhood of the disc and those derived from the choroidal circulation. It is possible that there may be a similar capillary anastomosis between the capillaries at the extreme periphery of the retina and those derived from the anterior ciliary vessels. Mr. Coverdale suggests that even without any capillary anastomosis there may be collateral vessels from the ciliary circulation in the neighbourhood of the disc, too minute to be detected with the ophthalmoscope. The nourishment derived from this very attenuated blood-supply is, however, so small that it is never sufficient to maintain the vitality of the ganglion cells, which die very shortly after their blood-supply is cut off. This explains the futility of any treatment in these cases after the first few hours. In the case already mentioned, where the attempt to move on the plug from the main artery to a peripheral one by means of massage and amyl nitrite, was successful, it was too late to restore the function of the retinal cells. When the patient has recovered from one or more short periods of temporary blindness in one eye, the treatment resolves itself into effort to prevent further disease of the vascular walls or of the nervous mechanism controlling them.

INSURANCE AND MATERIAL FACTS.

PERSONS who take out a policy of insurance are often puzzled to know how much information they should volunteer in answering the questions on the proposal form. They are probably aware that the law regards a contract of insurance as one in which the utmost good faith is essential. If there has been any concealment or misrepresentation of a material fact the contract becomes void. But it is not easy to know what facts the law will deem to be material. The answer depends on what a jury (or a judge exercising the functions of a jury) thinks as to whether the matter concealed or misrepresented would have influenced the mind of a reasonable and prudent insurer in the direction of either accepting or declining the risk. The point is neatly illustrated by a recent case in the Manchester County Court, reported in the *Solicitors' Journal.* A motorist had had two accidents through sudden illness causing him to lose control of his car. He claimed under his insurance policy, but it came to the knowledge of the insurance company that, since the war, he had occasionally suffered from attacks of biliousness which incapacitated him for the space of about an hour. His proposal form had included a question asking whether he or his chauffeur suffered from any physical infirmity; to this he had answered in the negative. The insurance company, regarding this as the non-disclosure of a material fact, sued him for the repayment of £56. The motorist explained that, when filling up the proposal form, he had not thought it necessary to mention the bilious attacks; he assumed that "physical infirmity" meant physical disability such as the loss of a limb; he said that, if he had been asked about his general health, he would have told the company about the biliousness though he regarded it as trivial at the time. The court held that the motorist's answer on the proposal form had been a true one. He had never suffered from these attacks until he left the army; he had had only four such attacks before signing the proposal form; it was seven years between the last attack and the date of the signature. The plaintiff company, the judge said, had not proved its case, but had been right to raise the issue which was a matter of public importance; there was a danger of proposal forms being too carelessly filled up, and also a danger of persons driving who were liable to lose control through no fault of their own. In our view an insurance company may be pardoned for regarding as a material fact a motorist's peculiar liability to sudden incapacitating illness. The learned judge, however, took a different view. As his decision is a decision on a question of fact, it is the more difficult to upset on appeal.

CHEMICAL BLOOD CHANGES IN ILEUS.

THE cause of death in ileus has long been debated. In a recent paper[1] Rudolf Brandberg traces the growth of the view that in experimental strangulation of the intestine death is due to intoxication from gangrenous bowel tissue alone or in conjunction with peritonitis. He notes that increasing support has lately been given to the theory that the chief lethal factor, at least in high obstruction where serious damage to the wall of the intestine is absent, lies in the loss of mineral substances and fluid. The idea underlying this theory is that the secretions discharged into the upper portion of the alimentary canal cannot be reabsorbed, and so are lost to the body. The normal amount of fluid excreted daily into the upper portion of the alimentary tract and reabsorbed in the lower is estimated to be equivalent in volume to the total amount of blood and lymph in the body, so that in high obstruction the mineral and fluid loss might be very great. These losses lead to chemical changes in the blood, particularly a reduction of chlorides, chiefly through loss of gastric juice, and an increase of non-protein nitrogen produced by loss of fluid. A series of experiments in rabbits have led Dr. Brandberg to favour this hypothesis. Animals with simple obstruction of the upper gastro-intestinal tract die very soon, and show at autopsy no important changes besides distension of the intestines above the obstruction. Examination of the blood between the time of operation and death shows a progressive fall in the blood chlorides and rise in the non-protein nitrogen, which changes coincide with extensive fluid and mineral loss. In pyloric obstruction copious quantities of chlorides are lost (about 600 mg.), but only small amounts of fixed alkalies (100 mg.). When the obstruction is just below the entrance of the bile and pancreatic ducts, the chloride loss is increased by barely 50 per cent., while the loss of fixed alkali rises to seven times the previous amount. This is probably the explanation of the old observation that obstruction at this point is most rapidly fatal. Towards the lower end of the small intestine obstruction causes much less fluid loss, because a certain area for reabsorption is available. Obstruction of the large intestine does not result in any appreciable loss of fluid or mineral substance, but all the animals were found at autopsy to have peritonitis arising from gangrene due to over-distension of the large intestine.

[1] Acta Chir. Scand., 1929, lxv., 415.

Dr. Brandberg has also investigated the blood chlorides and non-protein nitrogen in 36 cases of human ileus. Three cases of ileus of the stomach and duodenum showed on the third or fourth day of the disease a distinct non-protein nitrogen rise and chloride reduction. In 13 cases of obstruction of the small intestine a non-protein nitrogen rise could be demonstrated after two days, in 16 cases of strangulated hernia containing small intestine the non-protein nitrogen rise did not usually appear until the fourth day; in none of these 29 cases could any definite chloride reduction be demonstrated. In four cases of obstruction of the large intestine no blood changes occurred even after several days. The author emphasises the importance of knowing that in high intestinal obstruction a high non-protein nitrogen may be found in the blood so that an unjustifiable diagnosis of renal disease may be avoided. He does not contend that clinical examination of the blood is of much use in the diagnosis of intestinal obstruction, because the diagnosis should mostly have been made before these changes occur. The same changes may be manifest when either chloride or fluid is lost from other causes than obstruction. He suggests, however, that variations in non-protein nitrogen and in chlorides may have value in showing whether an obstruction has been successfully relieved at operation, for if continuity of the lumen has been re-established the biochemical abnormalities disappear; otherwise they become more pronounced. These investigations give additional justification for the subcutaneous administration of sodium chloride solution in intestinal obstruction, and indicate that larger quantities than are usually given might be tried.

BIOLOGICAL DIAGNOSIS OF PREGNANCY.

INQUIRIES have reached us from practitioners anxious to know where they can send specimens of urine for diagnosis of pregnancy, since the Zondek-Aschheim test is not yet at the stage where clinical pathologists accept material for investigation as part of their routine work. We understand that Dr. Dickens and Mr. Allan, who recorded a high percentage of informative results in last week's LANCET, do not undertake private work. However, we would recall to our readers a request made by Prof. F. A. E. Crew in THE LANCET of March 30th, 1929, for specimens for diagnosis. His requirements are 2 oz. of fresh morning urine in a chemically clean bottle enclosed in a package that will withstand the dangers of the journey and accompanied by the following information: Date of last menstrual period; parity; menstrual history; history of any severe medical disturbances. To cover the cost of the mice a charge of 5*s.* for private cases and 1*s.* 6*d.* for institutional cases is made; a postal order should therefore be enclosed in the package, which should be addressed to the Pregnancy Diagnosis Station, The University, King's Buildings, Edinburgh.

THE BRIGHTON EPIDEMIC.

THE people of Brighton and Hove have been suffering for some weeks from a distressing epidemic of sore-throats, which is now happily abating. The clinical course and the pathological features in typical and atypical cases are detailed by Dr. O. Wilberforce and Dr. Mary Leslie-Smith on another page. The onset has generally been sudden, with a temperature of 100° F. to 103° F., pain and swelling of the tonsils and cervical glands, and intense headache. Relapses after four or five days of normal temperature have been frequent. Fortunately chest complications have not been a feature of the epidemic. A heavy growth of a long chained hæmolytic streptococcus has been obtained in nearly pure culture from the throats of many of the victims, from peritoneal and empyema fluids, from the blood, and from a suppurating phlebitis. The search for the cause of the epidemic has been made by medical officers sent for the purpose by the Ministry of Health, working in coöperation with Dr. Rutherford Cramb, deputy medical officer of health for Brighton, and Dr. A. Griffith, medical officer of health for Hove. Dr. Cramb and Dr. Griffith stated on Jan. 5th that inquiry had been made into all probable causes, including the milk-supply. These pointed to the milk-supply from one dairy being infected. By examination of the milk from each farm serving milk to this dairy the infection was traced to a farm about 15 miles away. The milk from this farm was stopped on Dec. 28th. Since this statement was issued medical officers from the Ministry of Health have been endeavouring to trace the source of infection at the farm and the way in which the milk became contaminated. Swabs have been taken from individuals working at the farm and from cows, and the results should be known shortly. Meanwhile no fresh cases have been reported except among those in contact with sick people, and there is good ground for the hope that no more will occur.

AN ŒSTRUS-PRODUCING HORMONE IN CRYSTALLINE FORM.

FURTHER details of the new crystalline œstrus-producing hormone, whose isolation was noted by our Berlin correspondent last week, have now reached us. E. A. Doisy, at the Thirteenth Physiological Congress at Boston (August, 1929), briefly announced the preparation of a crystalline substance from the urine of pregnant women, of which about one-eight millionth of a gramme constituted one mouse unit. Now Dr. A. Butenandt, working in the Chemical Laboratory at Göttingen University, of which Prof. Windaus is director, gives some preliminary details of researches which have led to a similar result.[1] The full chemical and physiological work will follow in a forthcoming publication, but sufficient information is now available to show that the work is of great interest. The material from which the first start was made was a crude oil commercially prepared from urine of pregnancy, which had an average activity of some 30,000 mouse-units per gramme. A preliminary purification was carried out by distribution between two solvents for example, the aqueous-alcoholic solution was shaken with petroleum ether. A similar method has been used by Doisy.[2] The hormone remains in the aqueous-alcohol phase from which it may be shaken out with ether, benzene, or ethyl acetate. In this way the activity of the preparation is increased up to 500,000 mouse-units per gramme, and impurities are removed. At this stage systematic precipitation and adsorption having been found of no great use in increasing the purity, the action of acids and alkalies was tried. The fact that a part of the hormone can always be removed from its ether solution with alkali (cf. H. Allan, F. Dickens, E. C. Dodds, and F. O. Howitt[3]), leaving a residue in the ether which is insoluble in alkali, whereas the hormone in the aqueous alkaline extract after acidification can easily be extracted with ether, suggested to Dr. Butenandt the probability that the active principle is a lactone.

Working on this idea he arrived at a new process of purification. Neutral impurities are shaken out from the alkaline solution with ether, and the contaminating acidic substances remaining are removed by weak alkali. By the use of such methods he has obtained the substance as an alkali-soluble oil containing 1½ to 2 million mouse-units per gramme. The final stage of purification consists of distillation in a high vacuum and sublimation in vacuo or crystallisation from solvents. The hormone distils over in a vacuum of 0·02 to 0·03 mm. Hg at a temperature of 130-150°C., and then contains 5 million mouse-units per gramme. Long sublimation in high vacuum or treatment with solvents yields a well-crystallised material which, even after repeated recrystallisation retains its high activity of 8 million mouse-units per gramme. This means that 0·000125 mg. in a single injection (dissolved in sesame oil), brings a castrated mouse into the œstral state. The author considers that he has been successful in preparing the female sexual hormone in the pure crystalline state. The name "progynon" has been given by him to the crystalline substance of which the physical and chemical properties are as follows. It has the solubility characteristics of a lipoid. It is easily soluble in alcohol, acetone, chloroform, benzene, and hot ethyl acetate; it dissolves with more difficulty in cold ether, and sparingly in petroleum ether or in water. By sublimation it is obtained in beautiful, snow-like crystals. It may be crystallised from ethyl-acetate or dilute alcohol in colourless leaflets of characteristic shape, melting with slight decomposition above 240°. Progynon contains no nitrogen or sulphur, and the analysis and molecular-weight determinations suggest the formulæ $C_{23}H_{28}O_3$ or $C_{24}H_{33}O_3$. Chemical tests show that it has no protein or carbohydrate groupings, and it is considered that sterols or bile-acids represent possible constitutions. The solubilities and behaviour with acids and alkalis suggest a lactone constitution, whilst biological inactivation by phenyl cyanate is considered to be accounted for by the formation of a urethane (not isolated), which is inactive. Hydrogenation also destroys the activity.

[2] Jour. Biol. Chem., 1926, lxix., 357: 1928, lxxix., 53.

[3] Biochem. Jour., 1928, xxii., 1526.

The constitution of progynon stimulates interest in the researches of S. Loewe[4] and M. Dohrn[5] on substances which are claimed to have similar activities obtained from the vegetable kingdom are of interest, since lactones of this type are known to occur in plant tissues. These plant extracts, however, apart from some doubt as to their biological action, are oily substances. Up to the present, crystalline lactones from plant sources have been tried for their action on ovariectomised mice, but, up to the present, have been found inactive. The biological standardisation of progynon was carried out carefully on a number of mice (16 to 18), showing a continuous resting stage (i.e., diœstrus), by injection of the solution of progynon in sesame oil in a single dose. The reaction was taken as positive when 75 per cent. of the animals used showed a full œstral response.

MENTAL STRESSES OF SCHOOL LIFE.

To the eighteenth annual conference of educational associations, held at University College during the first week of January, the National Council for Mental Hygiene added its contribution by a discussion on preventable mental and physical strains of school life. Some people deprecate the fuss that is made over children nowadays, arguing that what was good enough for their parents should be good enough for the young, but Dr. W. Moodie maintained that the school-child of to-day is unusual and does demand special methods if the nation's mental health is to be established. Many of the emotional problems he mentioned have always been with us: the changes in outlook accompanying puberty, for instance, the emotional charge associated with the first sex knowledge, the effects of sex jealousy, and the death of relatives. The highly intelligent child of a poor home, worse dressed and supplied with less pocket money than his fellows, had always had to wrestle with the inferiority which he shares with the dull child. The child of unequally developed capacities—always, in Dr. Moodie's opinion, the result of some inborn difficulty which can be recognised and treated—has always suffered under the stereotyped curriculum. Nevertheless, to all these difficulties there is added a new factor for the war-baby and the air-raid baby, a factor which can best be summed up as a lack of that fundamental sense of security which is so essential for adequate adaptation to the environment. Man, it has been well said, differs from the animals chiefly in the long period for which he is dependent, and the growth of civilisation has steadily increased that period and in many ways made it lifelong. The division of labour on which modern states are founded makes all of us dependent on our fellows for important supplies, and we have all learned how to be dependent by the steady evolution of a most delicate sensitiveness to the feelings of others. Children have a peculiar power of "picking up an atmosphere," of realising the emotional attitudes of the adults around them. The children in our upper forms to-day were introduced into a world of disruption, anxiety, and insecurity, and they have absorbed that atmosphere into their very beings. Many of them have suffered from an inconsistent home discipline, almost unknown in the placid father-ruled homes of the last century. When they come to the alien environment and discipline of school they find it hard to adapt. Another new difficulty, pointed out by Dr. Doris Odlum, is the hostility towards the school often openly expressed by parents whose hopes for their offspring have been disappointed. This subjects the child to the stress of a divided loyalty, which is peculiarly distressing. The new organisations which strive to bring parent and teacher together will do something to prevent this lamentable state of affairs. Both Dr. Odlum and Dr. Crichton Miller attacked the school system as another source of strain: the high demand for intellectual achievement, the standardisation, the boredom of pseudo-fatigue induced by emphasis on book work, and the lack of frequent rest-pauses in a long day. Modern school inspection has gone far towards abolishing the physical stresses, but bad posture, defective vision, and toxæmia still have a place among the preventable stresses of school life. Even if the child is well looked after in school it often has to do homework in a bad light and a cramped position, amidst endless distractions. Dr. Odlum did not forget that, difficult as it may be to be a good parent, it is still harder to be a good teacher, and the task calls for an ability to subordinate his or her own personality entirely to the interests of the children—no mean demand.

Both Dr. Moodie and Dr. Crichton Miller emphasised the oft-forgotten truth that all these stresses may have positive value. No two children are alike or react alike, and a strain that will crush one child will be the making of another. The primary necessity is to recognise the individual misfits as they arise. Dr. Moodie pointed out the interesting fact that a sudden depreciation in the calculating power of a child is almost invariably due to an emotional problem and should always be a psychological danger sign. The child can only be educated as an individual, and this means the growth of a new spirit rather than any specific change in curriculum. If preventable stresses are constructively dealt with the personal problems of the children can be trusted to cure themselves.

MANCHESTER HOSPITALS.—The annual statement of the Manchester Voluntary Hospitals Committee deals with 17 hospitals and dispensaries. The ordinary expenditure of the year was £315,000, but extensions and other special outgoings increased the total to £340,000, which left a net deficit of £28,000. The annual subscriptions amounted to nearly £10,000 more than in 1924. Manchester Corporation contributed £8000 per annum to the support of these institutions, the largest grant being £2000 to the Royal Infirmary. Patients paid just on £18,000, and various public authorities contributed £34,000 in respect of other patients. The aggregate number of beds is 2160, 1883 of which are in average daily occupation. At the end of 1928 the accumulated deficiencies of the institutions amounted to £117,000.

Modern Technique in Treatment.

A Series of Special Articles, contributed by invitation, on the Treatment of Medical and Surgical Conditions.

CCXCVIII.

TREATMENT OF THE TYPHOID FEVERS.

PART II.*

Drugs.

FEW drugs are required in the routine treatment of typhoid fever. Hexamine is held to have a disinfectant action on bile, pancreatic juice, and urine; and for this reason it is good practice to prescribe it from the beginning of the second week onwards. A dose of grs. 20 or more is given three times in the 24 hours, together with sufficient alkali, say an equal quantity of sodium citrate and sodium bicarbonate, to make the urine strongly alkaline in reaction, lest strangury and hæmaturia result. The reaction of each specimen, as soon as it is passed, is tested with litmus and the dose of alkali adjusted accordingly. If signs of cholecystitis arise ten doses of hexamine, each of grs. 20, with sufficient alkali, are administered in the 24 hours, and antiphlogistine is applied over the gall-bladder region.

In an alcoholic subject it is advisable to allow whisky or champagne throughout the illness. The majority of patients do not require alcohol at any stage, but the drug is to be employed when the pulse frequency is increasing (apart from hæmorrhage) and the volume is small, and when signs of pulmonary congestion are present, but the effects of its administration on pulse and respiration must be carefully watched. It is best given as brandy or whisky; for a patient not addicted to alcohol an initial dose of two teaspoonfuls in an equal quantity of water every three hours, i.e., 2 oz. in 24 hours, will suffice. When the effect is beneficial the dose may be cautiously increased to 5 or 6 oz. in the 24 hours. One ounce of brandy at night may relieve delirium and induce sleep in appropriate cases. Brandy is also given when a rigor occurs during the disease. It is never added to a feed lest the whole of the prescribed dose be not taken.

Specific Treatment.

Specific therapy has a very limited field in typhoid fever. Serum of convalescent patients, in doses of 5, 10, or 20 c.cm. intramuscularly is advocated by Pezzi (*Riforma Med.*, 1922, xxxviii., 80). Vaccine both raw and sensitised has been employed. Achard recommends two or three doses of vaccine subcutaneously in the first few days, especially for children. Vaccine has been given intravenously. Gay (Typhoid Fever, New York, 1918) states that the milder cases of the disease react better to the treatment than the more severe, but even the most serious will, in some instances at least, be benefited and even aborted. The initial dose is 150 million; a chill follows the injection in from 15 minutes to an hour, and is accompanied by a rise in temperature of one to three degrees; within 12 hours the temperature may fall to normal with sweating, and usually improvement in such symptoms as headache and delirium is noticed. If the temperature again rises over a period of two or three days, a slightly increased dose is given. In Gay's series of 98 cases, one-third were aborted, one-third benefited, and the remainder were unaffected. The present writer has no experience of these "shock tactics" in typhoid fever, and the method has not been generally adopted.

In certain complications due to the specific organism of typhoid fever vaccine is undoubtedly of value; especially is this so in osteoperiostitis, chronic cholecystitis, and pyelitis. A dose of five million is given subcutaneously at the first sign of periostitis, and the dose doubled if need be five days later, heat meanwhile being applied to the part. Vaccine should be avoided in the presence of thrombophlebitis.

Certain Symptoms.

Severe toxæmia, headache, delirium, restlessness, and insomnia may be helped by hydrotherapy. The cold bath, under ordinary conditions, necessitates considerable disturbance to the patient, but when facilities exist it is to be recommended. The patient is let down into the bath on a stretcher or slung in a blanket, the temperature of the water being lowered from 95° F. to 70° F. or 65° F. by pouring cooler water over the neck and shoulders, 15 to 20 minutes being occupied in the process.

The cold pack is to be preferred in most cases; it may be given as follows:—

The patient is rolled on to a mackintosh covered with a blanket, and a towel is arranged around the hips; the bedclothes are removed, and the patient is covered with a blanket. Two large sheets are each folded into four thicknesses, and rung out of water at a temperature of 65° F. The blanket covering the patient is removed, one sheet passed under the patient, brought up round the body inside the arms and enveloping the legs; the second is applied to the front and tucked round the arms and neck; a warm bottle is applied to the feet. The patient is then covered with a blanket for five minutes, when the process is repeated; if the patient is very restless the sheets may be sprinkled with cold water instead of being removed. At the conclusion the patient is dried quickly, and the clothing replaced. The cold pack must not be given to feeble individuals or to the aged.

Antipyretic drugs are to be avoided in typhoid fever; the cold pack is the safest method to employ when hyperpyrexia is present. Severe headache, not relieved by hydrotherapy, is an indication for lumbar puncture. In toxæmia the drinking of water is to be specially encouraged. Insomnia, when not due to headache, may be relieved by bromide and chloral, say, grs. 30 of the former and grs. 10 of the latter, repeated hourly if necessary for four doses; when headache is the cause Dover's powder with aspirin is often efficacious.

Certain Complications.

Hæmorrhage.—Small hæmorrhages may occur from congested Peyer's patches towards the end of the first week; they are usually of no consequence. Large hæmorrhage from the erosion of a vessel in the base of an ulcer is rare before the eighteenth day. When a large hæmorrhage occurs, as may be shown by the presence of blood in the stool, and (or) by pallor, a drop in temperature with a rising pulse frequency, sweating, and shallow sighing respiration, the patient is kept absolutely quiet, and all food is withheld for 24 hours. Morphia is given hypodermically at once, and repeated as often as is necessary to keep the patient under its influence. The disadvantage of morphia (and heroin) in such circumstances is that if perforation follows the early signs are apt to be masked; the rapid sequence, though not very frequent, must be borne in mind. If the pulse is very small in volume, the foot of the bed is raised on blocks, and the extremities bandaged from below upwards. The patient is not to be put on a bed-pan, any discharge from the bowel being collected on tow. If peristalsis is active, it should be checked by a starch and opium enema (tr. opii ½ drachm in starch suspension 4 oz.). It is the custom to apply cold to the abdomen either by means of a Leiter coil or by an ice-bag suspended from a cradle; in either case the skin must be protected with flannel.

When a large hæmorrhage has taken place blood transfusion from a donor of the same blood group is probably the most valuable hæmostatic; it not only replaces a part of the blood lost, but it also increases the rate of blood-clotting. Not more than 300 c.cm. should be given at one time. Surgery has no place in the treatment of intestinal hæmorrhage in typhoid fever.

Perforation.—Treatment of perforation is immediate laparotomy. When perforation is suspected it is safer to explore than to await developments; in any case morphia is withheld until operation is decided on. A combination of local and general anæsthesia is recommended. The abdominal wall around the site of the proposed incision is thoroughly infiltrated with 0·5 per cent. novocain and 1 : 200,000 adrenalin; before the peritoneum is opened the subperitoneal tissue is similarly treated and the induction of nitrous oxide and oxygen anæsthesia begun. This procedure gives quite sufficient anæsthesia and is the safest under the circumstances. The incision is suprapubic, slightly to the right of the mid-line. The perforation is sewn up by Lembert's sutures; any fluid is withdrawn from the peritoneal cavity by suction apparatus or, failing that, by gentle mopping with a gauze swab. A soft drainage-tube is inserted if the peritoneum has been much soiled. Blood transfusion is advisable during, or immediately after, the operation. Peritonitis may occur apart from perforation, especially in paratyphoid fever.

---

* Part I. appeared last week.

Thrombophlebitis necessitates complete immobilisation of the limb by sand bags for a period of three weeks, after which gentle massage may be begun. The pain may be relieved by the local application of glycerin of belladonna, and the intravenous injection of grs. 20 of sodium citrate in 8 oz. of sterile water.

Ulceration of lymphoid tissue in the pharynx is a cause of dysphagia; the discomfort may be relieved by the use of a spray containing menthol grs. 3 and chloretone grs. 10 to the ounce of liquid paraffin.

Cardiac dilatation—as evidenced by outward movement of the apex-beat, softening and shortening of the first heart sound, and a falling blood pressure—if acute, calls for the intravenous injection of strophanthin grs. 1/200, repeated eight hourly if necessary, and the hypodermic administration of strychnine grs. 1/30 four hourly, alternately with pituitrin and adrenalin. Camphor grs. 3 in olive oil ♏15 is useful in an emergency, but is not suitable for repeated administration.

Meningitis, a rare complication, is treated by daily lumbar puncture; during the operation, for which a general anæsthetic is necessary if the patient be restless, the buttocks are raised slightly above the level of the head, and the fluid is allowed to flow so long as it will.

If *broncho-pneumonia* develops, the patient is given oxygen continuously by means of a No. 7 catheter passed through the nose. The catheter is changed every four hours, and the oxygen passes through the water in the Woulfe's bottle at such a speed that the bubbles can just be counted.

Bedsores readily form over pressure points when nursing is inefficient. When such complications as perforation and thrombosis arise to prevent frequent change in the patient's posture, especial care is necessary to avoid them—scrupulous cleanliness, drying the skin, hardening it with alcohol, and dusting with powder; when the skin is unusually dry lanoline may be substituted for powder. The draw-sheet is frequently changed and kept free from creases. The warning sign is a permanent redness of the skin; the area is then painted with collodion flexile. An abrasion is dressed with an emulsion of zinc oxide in castor oil, or dusted with bismuth formic iodide powder every two or three hours. An ulcer is fomented until sloughs have separated; the part is then dusted with B.F.I. powder and a smooth dry dressing applied and frequently changed.

A. E. GOW, M.D., F.R.C.P. Lond.,
Physician with Charge of Out-patients, St. Bartholomew's Hospital.

THE following articles in this series have appeared since the last collection was published as Modern Technique in Treatment, Vol. IV. :—

Special Articles.

MATERNAL MORTALITY
IN THE OBSTETRICAL AND GYNÆCOLOGICAL UNIT, ROYAL FREE HOSPITAL.

By DAME LOUISE McILROY, D.B.E., M.D.,
PROFESSOR OF OBSTETRICS, UNIVERSITY OF LONDON;
AND
BEATRICE TURNER, F.R.C.S. EDIN.,
OBSTETRIC REGISTRAR, ROYAL FREE HOSPITAL.

As so much public discussion has taken place lately on the subject of maternal mortality, it may be of interest to give the death-rate of mothers in a teaching hospital, and also an analysis of the causes of death. The Royal Free Hospital has 46 obstetric beds, and a district close to the hospital and a district clinic in Islington. About 90 per cent. of the patients are booked for admission from the antenatal clinics, and at the most about 10 per cent. are sent in as emergency cases. The cases of puerperal sepsis are treated in a ward completely isolated from the main block of wards, and there is an isolated department of five beds for obstetric patients with venereal disease. The cases of sepsis are treated by the senior staff, and the gynæcological house surgeon and gynæcological clerks only are in attendance. The students have three months as gynæcological clerks, non-resident, and three months residence as obstetrical clerks. The first month of clinical obstetrics is spent in the wards only, the second month at the district centre, and the third month in the hospital district and V.D. ward. There is a resident assistant who acts as tutor to the junior clerks. The clerks must personally deliver the cases for which they are signed up. The director, second and third assistants are whole-time officers, the first assistant is part-time. The assistant staff changes every two years, but the senior posts are filled up by candidates from the junior posts. There is, therefore, not the same continuity of treatment for patients as is obtained in hospitals where the staff remain for years. It is, however, one of the aims of the unit system to enable a larger number of young graduates to obtain experience in obstetric and gynæcological practice.

No. of Maternity Patients Delivered from Oct. 1st, 1921, to Oct. 1st, 1929.

Year.	In-patients.	District patients.	Total.	Deaths.
1921–1922	684	315	999	3
1922–1923	883	271	1154	2
1923–1924	944	217	1161	4
1924–1925	765	212	977	2
1925–1926	839	349	1188	4
1926–1927	778	435	1213	5
1927–1928	795	482	1277	2
1928–1929	929	570	1199	4
Total ..	6617	2951	9168	26

Total patients delivered in eight years = 9168.
Maternal deaths = 26. Maternal mortality-rate = 2·7 per 1000.

This maternal mortality report is based on deaths which have occurred during a period of eight years. 1921–29, and includes both in-patients and district patients. Although no deaths occurred in the

district, this may be accounted for by the fact that any patient seen at the district antenatal clinics with an obstetric complication is admitted when possible to the hospital for confinement.

Analysis of Cases of Maternal Deaths.

Six cases of death were attributed to obstetric shock, four to shock from hæmorrhage, six to sepsis, two to embolus, four to toxæmia and eclampsia, one to broncho-pneumonia, and one to acute appendicitis. The details of each of these cases are as follows.

Obstetric Shock.

1. Prim., aged 29. First seen 16th week. Previous health good. Pregnancy—carious teeth, slight œdema of legs, no albumin. Treated as antenatal out-patient. Delivery spontaneous at term. Labour: first stage, 27 hours; second stage, 2 hours; third stage, 40 minutes. Cervix rigid. Twins. P.P.H. Died 30 minutes after delivery from shock. Infants well.

2. Prim., 21. First seen 20th week. Had several attacks of bronchitis. Pregnancy—1 carious tooth. Second cardiac sound reduplicated. Treated as O.P. Delivery spontaneous at term. Labour: first stage, 35 hours; second stage, 2 hours; third stage, 1 hour. Cervix rigid. P.P.H. Died 15 hours after delivery from shock. P.M.: Fatty heart, old pleurisy and consolidation. Infant well.

3. Multip. (3), 26. First seen 12th week. First labour, forceps, craniotomy; second and third, Cæsarean section. Pelvis contracted. Toxæmia. Treated as antenatal in-patient and out-patient. Teeth good. C.S. performed at term. No complications, no hæmorrhage. Patient very excited some hours after, pulse feeble. Died in ten hours of obstetric shock. Infant well.

4. Prim., 33. Admitted as emergency for obstructed labour at term. First stage, 60 hours; second stage, 8 hours; third stage, ½ hour. Forceps. Craniotomy for disproportion. Dead fœtus. Sudden collapse and death. Obstetric shock.

5. Prim., 32. Induction at 38th week; rubber tube for disproportion. Cervix rigid, long labour, death of fœtus in uterus, craniotomy. Sudden collapse after delivery; death. Obstetric shock. P.M.: Fatty heart.

6. Multip. (3), 37. First seen 16th week, abnormally fat. Teeth good. Previous labours long, forceps; children, average weight 12–13 lb. Œdema, breathless, induction 38th week, rubber tube. Long labour. Forceps failed. Perforation. Cæsarean section, as delivery thought to be impossible. Dead fœtus. Died 3¾ hours later from obstetric shock.

Shock from Hæmorrhage.

7. Multip. (8), 41. Admitted as emergency 28th week. Severe hæmorrhage. Placenta prævia. Not in labour. Died 24 hours after admission. Shock from hæmorrhage. Not delivered. Packing. Version.

8. Multip. (2), 40. Admitted as emergency at term for severe collapse and abdominal pain. Intra-abdominal distension, signs of hæmorrhage, not in labour. Abdominal operation, cavity full of free blood, dead fœtus in cavity, ruptured interstitial pregnancy. Hysterectomy. Patient died shortly after, from shock, following hæmorrhage. Infant dead.

9. Prim., 36. Admitted as emergency near term. Severe A.P.H. Central placenta prævia. Not in labour. Cæsarean section. Secondary hæmorrhage later. Died in 17 hours from shock, following hæmorrhage. Stillbirth.

10. Multip. (5), 37. First seen 26th week, some toxæmia Previous labours normal. Had slight A.P.H. Placenta prævia, in ward one month before term. Further hæmorrhage, version about to be performed. Patient died under anæsthesia. Heart failure. Shock following hæmorrhage. P.M.: Fatty heart only found.

Sepsis.

11. Multip. (3), 37. First seen 37th week. A.P.H. Placenta prævia, not in labour. Carious teeth, systolic murmur. Packing. Version. Labour 1 hour 20 minutes. Sepsis. Broncho-pneumonia. Died 22nd day after delivery. Infant lived 14 hours.

12. Multip. (4), 32. First seen 36th week. Had sepsis second confinement. Contracted pelvis. Teeth artificial. Induction by rubber tube. Labour: first stage, 4 days; second stage, 2 hours; third stage, few minutes. Sepsis, jaundice, broncho-pneumonia. Death 21 days after delivery. Stillbirth.

13. Multip. (5), 40. Emergency, abortion at 4½ months, 28 days previously. Placenta retained, foul discharge, rigors, carious teeth, placenta removed. Died from sepsis 28 days after admission.

14. Prim., 25. First seen 37th week. Previous health good except rickets, flat pelvis, carious teeth. C.S. at term, no complications. General peritonitis. Death 17 days after operation. Infant well.

15. Prim., 20. First seen 36th week. Previous health good. Teeth carious. Ovarian cyst. Removed two days later. Labour began two days after. Delivery by forceps. First stage, 7 hours; second stage, 2 hours; third stage, 5 minutes. Died third day after delivery, peritonitis. Infant premature, stillbirth.

16. Prim., 25. First seen 16th week. Flat small pelvis. Teeth artificial. Septic sinus in knee from old operation for patellar complication. Treated during pregnancy, healed before term. C.S. after test labour. Died sixth day; general peritonitis. Infant well.

Embolus.

17. Multip. (1) (stillbirth), 35. First seen 34th week Previous health bad. Malaria, dysentery. During pregnancy had anæmia and diarrhœa. Exhaustion early in labour. C.S. at term, no complications. Slight pyrexia first week, normal temperature second week. Sudden collapse; died in few hours, 13 days after delivery. Pulmonary embolus. Infant well.

18. Prim., 38. First seen 14th week. Very nervous. Carious teeth. Toxæmia, later had persistent vomiting. Treated in ward, much improved. Died suddenly 14 days after admission. Emboli found in lungs.

Toxæmia and Eclampsia.

19. Prim., 28. First seen 18th week. Had appendix removed *four years before. Carious teeth.* Small pelvis. Disproportion later. Labour at 38th week. Forceps delivery. First stage, 34 hours; second stage, 6 hours; third stage, 35 minutes. Rigid cervix. Exhaustion. Jaundice second day, comatose. Died of *acute toxæmia*, hepatic atrophy, fifth day after delivery. Stillbirth.

20. Multip. (1), 31. First seen 20th week. First child, breech, stillbirth, jaundice in puerperium. Generally contracted pelvis. Teeth good. Induction 38th week, rubber tube. Labour, forceps. Difficult extraction. First stage, 12 hours; second stage, 7 hours; third stage, 10 minutes. Vomiting, jaundice, melæna, collapse. Died six days after delivery of acute toxæmia. Stillbirth.

21. Prim., 22. First seen 32nd week. Previous health good; œdema legs and abdominal wall. Albumin. Labour at term. Spontaneous delivery. First stage, 11 hours; second stage, 5 hours; third stage, 10 minutes. Four fits occurred within 12 hours of delivery. Recovery. Five days later, sudden severe headache, comatose. Death in 12 hours, acute toxæmia. P.M.: Œdema of lungs and brain present. Uterine muscle healthy. Infant well.

22. Prim., 22. First seen 35th week. Positive Wassermann, no albumin. Teeth good. Delivery spontaneous at term. Labour: first stage, 8 hours; second stage, 1 hour; third stage, 20 minutes. Eclamptic fit two hours after delivery. Several fits, coma began after fourth fit. Died four hours after delivery, 27 fits in all. P.M.: Hæmorrhages in liver, fatty changes. Infant well.

Broncho-pneumonia.

23. Multip. (1), 33. First seen 26th week. Had C.S. previous confinement. Carious teeth. Contracted pelvis. Labour at term, long, spontaneous. First stage, 26 hours. second stage, 1 hour 10 minutes; third stage, 15 minutes; Influenza and broncho-pneumonia third day. Died tenth day after delivery. P.M.: Double empyema and consolidation both bases. No pelvic sepsis. Infant well.

Heart Disease.

24. *Multip. (3), 28. First seen 28th* week. Pneumonia five years before. Chronic bronchitis. Heart trouble three years. Admitted at once, breathless, cough, respiration, distressed. Œdema. Improved for a time on treatment. Died five days after admission, undelivered. P.M.: Mitral stenosis. Broncho-pneumonia both lungs.

Acute Appendicitis.

26. Prim., 27. Admitted as emergency. Thought to be A.P.H. concealed. Twenty-fourth week acute abdominal pain present several days. No evidence of hæmorrhage. Pyrexia, patient very ill. Distended abdomen. Under

anæsthesia. Swelling in right iliac fossa. Appendicitis diagnosed. Lateral incision, large quantity of pus evacuated, drained. Death few hours later. At P.M. perforated appendix found.

Remarks.

The total number of antenatal attendances between 1921 and 1929 was 49,047. Among the cases treated in hospital there were 77 cases of placenta prævia, 21 cases of eclampsia, 10 cases of craniotomy (fœtus dead in every case before operation), 476 cases of forceps, giving 5 per cent. of all deliveries, and 152 cases of Cæsarean section, giving 1·6 per cent of all deliveries.

Fœtal deaths.—The number of infants born alive was 9152; neonatal deaths, 145; total number of stillbirths, 366 (of these 199 were at term and 167 premature). There were 112 sets of twins (1·1 per cent. of all deliveries). Abortions and induction of abortions are not included in the present report, except in the one case (13) where maternal death occurred.

Maternal deaths.—An equal number of deaths occurred among the primiparæ and multiparæ. The primiparæ preponderate only in the toxæmia group. The greater number of deaths were due to obstetric shock, which included deaths due to hæmorrhage and heart failure. The cases of puerperal sepsis show that operative interference and complications at labour increase to a great extent the risk of sepsis. Two of the patients died from sepsis after Cæsarean section, one after an operation for ovarian cyst. Bronchopneumonia is a serious complication in sepsis. Any septic focus requires consideration. One of the patients suffered from a septic sinus of the knee. Carious teeth should be attended to in every patient undergoing an antenatal examination. Most cases of toxæmia have some dental sepsis. Extraction or dental treatment is carried out in over 70 per cent. of the patients treated in the antenatal clinics. No case of abortion can be traced to dental treatment, but many abortions owe their origin to caries of the teeth. Since the case of No. 13 treatment by immediate removal of the placenta has been abandoned, and the patient's immunity is raised by serum, quinine, and glycerin drainage before the placenta is taken away. Every attempt is made to prevent general infection. No deaths have occurred since this method of treatment has been adopted.

Deaths from accidental hæmorrhage are rare since antenatal treatment has been carried out. In some cases of toxæmia the condition is so acute and rapid that treatment is of little avail. The fulminating type of eclampsia is an example. A very large number of patients suffering from serious heart disease are treated in the maternity wards. The results will be published separately; their success is due to the early recognition and treatment of the condition. An antenatal heart clinic is held once a week; this was started by Dr. Dorothy Hare and is now under the care of Dr. Olive Rendel. The cases are carefully examined and, if necessary, are electrocardiographed by Dr. Jenner Hoskin and Dr. Rendel.

A number of pregnant women lose their lives not from obstetric complications alone, but from general diseases, such as nephritis, phthisis, &c. We feel strongly that a very large measure of our low maternal mortality is due to our advantage in being a department in a general hospital and not an isolated maternity institution. Every member of the staff has helped us to safeguard the lives of the mothers by efficient medical, surgical, dental, and electrical treatment. Our diagnosis is made much more accurate in antenatal cases by enlisting the skill of the staff of the X ray and pathological departments. Cases of toxæmia are recognised early by biochemical examinations made by Dr. Pillman Williams.

Criticism is often levelled at institutional treatment for obstetric patients and the risk of sepsis in segregated patients is emphasised. A study of this report should show that wherever any complication is foreseen in a pregnant woman the safest place for her is in the wards of a hospital.

A RECENT EPIDEMIC OF SORE-THROATS IN BRIGHTON AND HOVE.

BY OCTAVIA WILBERFORCE, M.R.C.S.,
ASSISTANT PHYSICIAN, NEW SUSSEX HOSPITAL FOR WOMEN, BRIGHTON;
AND
MARY LESLIE-SMITH, M.B., B.S.,
PATHOLOGIST TO THE HOSPITAL.

IN view of the conflicting accounts which have recently appeared in the lay press about the Brighton and Hove "mystery disease," it may be of interest to record the following facts in connexion with an epidemic which seems to have been rather widespread in this locality but is now happily coming to an end.

Onset.—Clinically the onset has been sudden and in the majority of cases characterised by flaming red painful throats. Some patients have enlarged tonsils which show patches, and have pain on swallowing, definite swelling of the tonsillar and cervical glands, a very dirty dry tongue, intense headache, and, occasionally, a sense of suffocation where the larynx has also been involved. With many patients the temperature has risen on the first day to about 103° F., in others a beginning temperature of 100° F. has been followed after 48 hours by a rise to 103° F. or more. The pulse in most cases has not been unduly rapid. Sleeplessness due to the intensity of the backache and painful throat and neck region has been a most distressing symptom. Pain in the limbs and headache have been not infrequent complaints, although often absent. A troublesome feature of the disease has been the frequency of relapse after four to five days of normal temperature. Sometimes the relapse has been demonstrated merely by exacerbation of fever and fresh swelling of the glands, in other cases by the formation of localised pus. The actual pain of the cellulitis in the neck region has commonly radiated up the side of the head, into the ear, or over the whole area of the trigeminal nerve, when it has been particularly prostrating. Chest complications have been surprisingly rare.

On the whole, adults have appeared to suffer more from a general septicæmia, whereas children have had more localised troubles with rather fewer relapses. In a well-to-do girls' school, where 23 out of 40 boarders were afflicted, only two girls became seriously ill—a somewhat surprising fact since an increased virulence is commonly expected as when a number of people live together as a community.

Atypical Cases.

Two cases are perhaps worth recording as being atypical.

CASE 1.—A woman, aged 57, who has Paget's disease (with typical skull X ray changes), sent for one of us (O.W.) on Dec. 1st. She had vomited profusely the previous day, felt very ill and collapsed, with severe abdominal pain, and complained also of a sore-throat. Her temperature was 98° F., pulse 100. Abdomen tense, distended and tender all over. Throat red, swollen, patches over both tonsils, and a dirty tongue. Throat swab culture was negative to K.L.B., but grew a long-chained hæmolytic streptococcus.

Dec. 2nd: Patient continued to be very ill, vomiting at intervals. Much difficulty in keeping anything down, abdomen still painful and distended, no rise of temperature, pulse 100. B.N.O. Poor result from soap enema. *3rd:* Temperature rose to 103° F., pulse 112, on her left cheek a small patch of erysipelas developed. *4th* and *5th:* She grew steadily worse. Temperature rose to 105·2° F., the rash spread over both eyes, cheeks, ears, scalp; she appeared very ill, and was delirious and incontinent. Two doses of antistreptococcal serum (erysipelas), B. W. & Co., were given on Dec. 8th and 9th, and by the 11th her evening temperature had dropped to 98·6° F., pulse 80. She left the nursing home on Dec. 21st with a perfectly clear skin, having had no relapse. She enjoyed a Christmas dinner, though considerably self-conscious at having lost all the hair from her head.

The death-rate from pulmonary tuberculosis was the same as in 1927 and compared favourably with the average rate for the past ten years, whilst the non-pulmonary tuberculosis rate was lower than ever before. Details are given of the successful operation of the county scheme during the year. Out of 9470 patients on the register 6122 received some form of treatment under the scheme. Every effort is made to keep the accommodation in the county sanatorium at Lenham for patients in the early stages of the disease. Dr. F. J. Pierce, the medical superintendent, reports that of the special forms of treatment artificial pneumothorax gave the most satisfactory results. Of the 380 patients discharged during the year 30·5 per cent. were classified as quiescent; 47·1 per cent. as improved; 20·0 per cent. as not materially improved; and 2·4 per cent. died in the institution. Arrangements are made with various hospitals in the county for X ray diagnosis and light treatment. Forty-five patients were treated by Finsen light for lupus and tuberculous skin diseases at London hospitals, and when necessary the county council provided travelling facilities and for the boarding out of patients near the hospital. Dr. Charles Roper, tuberculosis officer for the Rochester district, makes special reference to the difficulty in removing from the register patients who have been "labelled" as tuberculous and are really old-standing cases of pulmonary fibrosis, bronchiectasis, asthma, and chronic bronchitis. The number of patients attending the V.D. clinics for syphilis has been fairly constant during the past six years, but the numbers of gonorrhœa patients and patients with "diseases other than venereal" have shown a tendency to increase. The number of attendances has considerably increased, but 26 per cent. of the syphilis patients and 12 per cent. of the gonorrhœa patients cease attendance before completing the course of treatment.

The work of the county pathological laboratories has been much appreciated by the medical practitioners, and the total of 33,005 examinations exceeded the previous record by 4544. The county scheme for crippled children has 48 beds for tuberculous and 32 for non-tuberculous cripples at the Alexandra Hospital, Swanley, where education is provided for children of school age, while three other hospitals at Maidstone, Canterbury, and Dartford provide beds for short stay cases. These three hospitals have established seven out-patient clinics in various parts of the county which are attended by their orthopædic surgeons. The new patients attending these clinics during the year numbered 414. The new houses erected numbered 6617—a marked decline as compared with the previous year's figure of 9023. The shortage of houses is estimated at 5000—i.e., only a little better than it was five years ago.

Nottinghamshire.

Dr. Christopher Tibbits presents the report for a period during which he held only a partial responsibility, owing to the death of his predecessor, Dr. T. E. Holmes, after a short illness on Dec. 24th, 1928. He mentions that a new child welfare and school centre is to be established at Stapleford, and that provision has been made for the removal of the health department staff to more commodious premises. The increased work of the department calls for an enlarged staff. A difficulty has arisen owing to the shortage of midwives, nurses, and health visitors, and as a temporary solution pupil health visitors are being taken. The maternal mortality-rate is slightly in excess of the figure for the whole country and Dr. Tibbits puts among the urgent needs adequate antenatal supervision, with the services of consultants available; hospital provision for complicated cases and those in unsuitable homes; hospital beds for puerperal sepsis; an adequate rural midwifery service; and dental treatment for expectant mothers.

Most of the midwives in the county have acquired some proficiency in antenatal work. They are advised to persuade their patients to obtain medical antenatal examination at least once; and that they are alive to the importance of antenatal work is indicated by the fact that of the 1500 cases in which they summoned medical help during 1928 abnormalities of pregnancy were the reason in 288 instances. Notification of puerperal fever is incomplete. In 1928 there were 14 notifications and 13 deaths and in 1927 10 notifications and 12 deaths. A special report by one of the county consultants, Mr. A. M. Webber, F.R.C.S., gives the particulars of 10 county cases of puerperal pyrexia treated by him, mostly admitted to the General Hospital, Nottingham, with 3 deaths. As a rule in "positive blood cases" Mr. Webber finds blood transfusions give gratifying results but they did not do so in this particular series. Intrauterine glycerin douches gave successful results and anti-scarlet fever serum appeared to be beneficial. Dr. Webber points out that for these elaborate methods of treatment immediate admission to a hospital is essential.

The Ransom sanatorium maintained by the county council has 130 beds and more accommodation is needed, particularly for cases of early tuberculosis in female adults. Decision as to this and other matters is deferred owing to the pending transfer of institutions to the county council. Dr. Tibbits points out that a more comprehensive procedure is needed with regard to the Milk and Dairies Order. The county veterinary officers examined 3085 animals and found 160 (or 5 per cent.) suffering from tuberculosis. About half of them were cows in milk, and most of them were in an advanced stage of the disease. Four complaints were received from the L.C.C. as to tuberculous milk and in each case the source of infection was traced. The prevention of the pollution of rivers was pursued more effectively owing to the appointment of a full-time rivers' inspector. But there is very much more to be done before the streams of the county can be considered satisfactory. Dr. Tibbits deplores the fact that the streams are used for the disposal of all kinds of refuse and suggests that the Rural Community Council through its series of lectures and the schools might endeavour to prevent this state of affairs by stirring up local pride and jealousy for the preservation of rural amenities. Industrial concerns appear to be coöperating well but the treatment of the waste from the two beet sugar factories is still in the experimental stage, and among other sources of pollution needing attention are coal washings, oil and the effluent from paper mills. The hydrographical survey of the Trent during 1928 showed the dominating influence of the pollutions from the potteries, the River Tame, and the Burton areas with a gradual improvement below these points and until in the Nottinghamshire area the average oxygen saturation value becomes 83·5 per cent. Private enterprise mainly with State assistance was responsible for 80 per cent. of the new houses erected in 1928. Eight grants were approved amounting to £1490 under the Housing (Rural Workers) Act, 1926. One was for the conversion of an old manor house into three cottages, another for the conversion of a barn into four cottages, and six were for the improvement of old cottages.

Warwickshire.

Dr. A. Hamilton Wood's report shows that the epidemic of small-pox which began in the last quarter of 1927 continued during the early months of 1928, when 124 cases were notified and four deaths were registered. Immunisation schemes against diphtheria have not yet been introduced in the administrative county, although this preventive measure is being used in Birmingham and Coventry. There were 18 notifications of encephalitis lethargica and 15 deaths. There were two deaths at the period 1 to 2 years; two at 2 to 5; three deaths at 5 to 15; two at 15 to 25; one at 25 to 45; and five at 45 to 65.

Inquiries were held for improvement schemes for the sewage works of Nuneaton and Coventry. The county staff has made surveys of the rivers Tame and Avon and their tributaries in coöperation with the Ministry of Agriculture and Fisheries, and the attention of eight authorities has been drawn to defects in sewage disposal works. During the year 99 routine samples of milk were examined for tubercle, of which 10 were found to be infected. Fifty-one notifications of tubercle-infected milk were received, most from outside authorities, and as a result 29 cows were slaughtered under the Tuberculosis Order. There are three producers of "Certified" milk and four of "Grade A (T.T)." Of 79 samples of milk examined for the presence of dirt eight were unsatisfactory. Bramcote Sanatorium was used for advanced cases of tuberculosis until January, 1928, when it became needed for its original purpose—small-pox. Provision was then made of 40 beds for advanced cases of consumption at the Memorial Sanatorium, Warwick. Even with this accommodation there is a considerable waiting-list and probably some of the poor-law hospital accommodation will be utilised for this purpose after the transfer, with the additional advantage that the beds for the advanced cases will be brought nearer to the relatives. The extension of the boundaries of Coventry involved the transfer of 74 patients on the register. The seven dispensaries are managed by the Warwickshire and Coventry joint committee. The contacts examined are few in number, 323, but showed an increase over the 1927 figure of 266. Of the 323, nine were tuberculous and one doubtful. Seven of the patients attending these dispensaries were having artificial pneumothorax treatment. Since 1927 the joint committee has made arrangements for other operative treatment at a London hospital—viz., pneumolysis, division of the phrenic nerve, and thoracoplasty—and during the year one patient underwent pneumolysis and three thoracoplasty with satisfactory results up to the present. There were 25 notifications of puerperal sepsis with 13 deaths, but some of the 44 notifications of puerperal pyrexia were really sepsis cases, thereby reducing the high case fatality. The total births numbered 6099, and 306 expectant mothers were on the register of the five county antenatal clinics. Dr. Wood recommends the county council to compensate the midwives for the loss of fees resulting from sending their abnormal cases to the clinics.

The orthopædic scheme has been extended by the inclusion of the orthopædic hospital at Coleshill and the opening of the outclinics at Coleshill and Stratford-on-Avon. The needs of the north of the county are also being met by the establishment of an outclinic at Tamworth. The progress of the scheme is indicated by the increase of cases dealt with to 580 from 312 in the previous year.

Interest and enthusiasm in maternity and child welfare work has been stirred up during the last three years by the Warwickshire Federation of Infant Welfare Centres, and this federation has recognised the long service of the county superintendent of midwives and health visitors by providing an artistic bronze shield, "the Mildred Lowe Shield," for competition annually among the voluntary infant welfare centres. Dr. Wood describes the continuing housing activity as "indeed encouraging." Of the 2385 new houses, 1711 were State assisted, 600 provided by local authorities, and 1111 by other enterprise.

Gloucestershire.

Dr. J. Middleton Martin mentions as a sign of increasing interest in the M. & C.W. work the appointment of Dr. E. Catherine Morris Jones as assistant medical officer and the formation of a federation of welfare centres early in 1929. Up to now the number of centres, 29, is comparatively small, and it is hoped that the federation will be instrumental in opening many more. Progress has been made in the pooling of hospital accommodation, and further progress is expected in the districts to the west of the Severn. Adequate water-supplies are to be provided for two parts of the county badly in need of such—viz., Coleford urban and West Dean rural districts and Cleeve Hill in the Winchcombe R.D.

Temporary appointments have been made to fill two death vacancies with a view to effecting another combination of districts for the appointment of a whole-time medical officer of health. Such combinations at present cover two-thirds of the county, and there are 12 part-time medical officers of health for the remaining 14 districts.

The services of obstetric consultants have been extended to include difficult labour. During 1927 there were eight consultations for pyrexia and three for pregnancy and confinements, whilst during 1928 the figures were 10 and 4. Less reluctance is shown in taking advantage of in-patient treatment for confinements. Thus during the last four years the number of hospital admissions for confinements has increased gradually from 18 to 60; and during the last two years 13 cases were admitted for pyrexia. A tabular statement shows the development of the midwifery service since 1905. In 1905 there were 53 trained and 175 untrained midwives; in 1928 there were 235 trained and 17 untrained. In 1905 there were 174 parishes covered by district midwives; now 327 are covered. During 1921–25 the midwives sent for medical help in 25·1 per cent. of their cases; for 1926 the figure was 32·9 per cent.; for 1927, 34·0 per cent.; and for 1928, 39·2 per cent. Dr. Martin draws the conclusion that this rise indicates improved attendance on mothers and infants. During recent years the midwives have attended two-thirds of the mothers in the county in their confinements. In the investigation of the 23 maternal deaths, Dr. Martin mentions that he received the willing coöperation of the doctors, the principal assigned causes being puerperal fever, 9; eclampsia, 6; and postpartum hæmorrhage, 3. The chairman of the public health committee (Rev. R. H. M. Bouth) is also chairman of the County Association for the Blind, which administers the approved scheme. On March 31st, 1929, there were 591 blind on the register and 129 cases under observation. There are 105 voluntary workers, who keep in touch with the blind persons in their neighbourhood. The workshops for the blind at Cheltenham were taken over by the county council in April, 1928. The scheme for the extension of medical services has made further progress. There are now 12 outstations, and the hospital accommodation available in addition to the general hospitals at Bristol, Cheltenham, Gloucester, and Stroud includes three smaller institutions in other parts of the county. Twelve additional outstations are to be opened during the next three years. The patients treated increased from 316 in 1927 to 390 in 1928, largely owing to the opening of the new outstation at Lydney. Forty-nine cases were admitted to hospital for operative treatment and 10 per refitting, &c. Cases who have passed out of the scheme by reaching the age of 14 have been kept in touch with, and Dr. Martin pleads for an extension of the age limit. An extra orthopædic nurse has been appointed to ensure following up. The cases treated included flat feet, 89; bow legs, 75; infantile paralysis, 47; congenital talipes equino varus, 22; cleft palate and harelip, 14; and scoliosis, 13.

The estimated deficit of 6400 houses made in 1919 is being gradually reduced, but on the other hand little has yet been done to improve existing houses, and Dr. Martin thinks that in this direction lies the most useful opportunities for improving the general standard of housing. Such restorations require ingenuity in order to preserve local characteristics, and the Council for the Preservation of Rural England has established panels of architects, who are willing, without charge, to assist local authorities and others in the general preservation of the amenities of rural areas in connexion with the Housing (Rural Workers) Act. So far Gloucestershire has done very little under this Act. In 1927 there were 12 applications and four agreed grants; and in 1928 there were 9 applications and two agreed grants.

The county analyst's report shows that 74 out of 485 milk samples submitted were adulterated. This represents 15·3 per cent. and is very much higher than the figure for the whole country, which for the year 1927–28 was 6·9 per cent. The most serious case of adulteration was one where samples were taken in course of delivery under contract, and the four churns were found to contain 26·9 per cent., 19·1 per cent., 51·3 per cent., and 18·7 per cent. added water, and also to be deprived of about half of their cream. This vendor was fined £10 in each case and £14 14*s.* costs, making £54 14*s.* in all. Twenty-eight cases of adulteration were taken before the magistrates and conviction obtained in 25. In two cases the vendor asked for "appeal to the cow" samples to be taken, and it was found that the cows were giving poor milk corresponding to the samples. Four surveys of dairy cattle by the veterinary inspectors have revealed 285, 264, 179, and 162 tuberculous animals, including 55, 32, 29, and 15 cases of tubercle of the udder. The cows examined numbered 52,131, 53,623, 44,648, and 42,126.

INFECTIOUS DISEASE IN ENGLAND AND WALES DURING THE WEEK ENDED DEC. 28TH 1929.

Notifications.—The following cases of infectious disease were notified during the week:—Small-pox, 232; scarlet fever, 2538; diphtheria, 1495; enteric fever, 36; pneumonia, 1019; puerperal fever, 32; puerperal pyrexia, 89; cerebro-spinal fever, 3; acute poliomyelitis, 4; acute polio-encephalitis, 1; encephalitis lethargica, 12; continued fever, 1; dysentery, 8; ophthalmia neonatorum, 76. No case of cholera, plague, or typhus fever was notified during the week.

The number of cases in the Infectious Hospitals of the Metropolitan Asylums Board on Dec. 31st–Jan. 1st was as follows: Small-pox, 415 under treatment, 13 under observation (last week 367 and 5 respectively); scarlet fever, 2729; diphtheria, 2743; enteric fever, 33; measles, 736; whooping cough, 135; puerperal fever, 24 (plus 12 babies); encephalitis lethargica, 118; poliomyelitis, 2; "other diseases," 15. At St. Margaret's Hospital there were 12 babies (plus 6 mothers) with ophthalmia neonatorum.

Deaths.—In the aggregate of great towns including London there was no death from small-pox, 3 (0) from enteric fever, 47 (17) from measles, 10 (5) from scarlet fever, 18 (3) from whooping-cough, 64 (9) from diphtheria, 50 (7) from diarrhœa and enteritis under two years, and 58 (8) from influenza. The figures in parentheses are those for London itself.

Wigan reported 8 deaths from measles; West Ham, Manchester, and Merthyr Tydfil, each 4. Of the 43 deaths from diarrhœa outside London 10 came from Liverpool, 5 from Salford, and 3 from Preston. Brighton records only 1 death from influenza (against 8 last week), Manchester 5, Portsmouth, Stoke-on-Trent, Liverpool and Sheffield, each 3.

The number of stillbirths notified during the week was 267 (corresponding to a rate of 61 per 1000 births), including 52 in London.

GREENOCK AUXILIARY HOSPITAL.—The new hospital which has been erected at a cost of £60,000 as an auxiliary to Greenock Royal Infirmary was opened recently by Miss Rankin who, jointly with her brother, Mr. Matthew Rankin, gave £20,000 as the nucleus of the fund for building, equipment, and endowment. There are two wards to accommodate between 20 and 30 men and women convalescents from the infirmary, and 18 private and semi-private rooms for paying patients.

DONATIONS AND BEQUESTS.—Lady Cargill, of Kelvinside, Glasgow, among other bequests, left £3000 to the Glasgow Royal Maternity and Women's Hospital, including a sum for the endowment of a bed to be called "The Mary Hope Cargill Bed," £2000 to the Royal Samaritan Hospital for Women, Glasgow, £1000 to the Royal Hospital for Sick Children, Glasgow, and £500 to the Glasgow Royal Cancer Hospital.—Mr. Arthur Sale, of Wallington, Surrey, among other bequests, left £1000 to the Derbyshire Royal Infirmary; £500 to the Royal Hospital for Incurables, Putney; £100 to the London Hospital.—Lieut.-Colonel W. B. Brocklehurst, of Butley Hall, near Macclesfield, left £1000 to the Macclesfield General Infirmary Endowment Fund.—Dr. W. R. Ashurst, of Farningham, Kent, left over £100,000 for charity, the participating institutions including the Lock Hospital, Association for Promoting the General Welfare of the Blind; Free Home for the Dying, Clapham Common, British Hospital and Home for Incurables, Streatham, Middlesex Hospital, Charing Cross Hospital, and St. Mary's Hospital.

BAD RADIOGRAMS.

To the Editor of THE LANCET.

SIR,—Your leading article in the last issue on The Coming of Radiology is of special interest to those who have followed the recent discussions and letters on this subject.

One very vital aspect of the case, however, seems to me to have been overlooked—namely, the pre-eminent importance of an X ray film which is technically and photographically of high standard. It is a regrettable fact that many very poor general and dental radiograms are still being produced, and the natural result is that the dental surgeon, the general practitioner and the patient are not thereby encouraged to utilise radiology to its fullest extent. A poor film may be more of a hindrance than a help; it cannot be "explained" to the patient, a large and increasing number of whom insist, justifiably in my opinion, upon seeing what are, after all, photographs of themselves for which they have paid a fee. Let me, however, emulate Agag, and tread delicately over this controversial topic!

I contend that a greatly extended use of radiology would be made if a more uniform standard of excellence could be relied upon. This is no insuperable obstacle as thousands of first-class radiograms are taken daily.

I am, Sir, yours faithfully,
J. D. KIDD, M.B., D.M.R.E.Camb.

Cavendish-square, W., Jan. 6th, 1930.

THE BRUIT D'AIRAIN.

To the Editor of THE LANCET.

SIR,—I am indebted to "Anglo-Gallicus" for his kindly remarks and criticisms of the paper on the Bruit d'Airain, or Coin Sound, by Dr. Dix-Perkin and myself. From the internal evidence of his letter I would deduce that he is a Saint-Bartien, if I may be allowed to coin an Anglo-gallicism. But this is by the way.

I feel that the main point of our work has not "got across," as our American friends would say. The fact that coins are not essential for the production of the bruit d'airain is a minor point of our thesis. This fact is known, or should have been known were it not that the bruit d'airain is called the coin sound in this country. What we did try to show were the reasons why the bruit d'airain is heard in some cases and not in others. I do not propose to take up your space by restating them.

Admittedly Laennec recognised the tinkling qualities of a pneumothorax cavity, but the sound obtained by percussion over a *tonneau vide* does not constitute a bruit d'airain, which did not, as "Anglo-Gallicus" pointed out, become a definite entity until Trousseau described it. We should, perhaps, have made the point clearer.

But I feel that I must cross swords with "Anglo-Gallicus" about the translation of *airain*. It does mean bronze, but it also means brass. In most languages many words have varying shades of meaning. The French word *bronze* most commonly means bronze, but in one connexion it must be translated by brass. *Airain* means (1) brass, (2) bronze, (3) bell-metal, (4) gun-metal. In one of its figurative senses it means boldness—e.g., *avoir un front d'airain* means "not to blush at anything," or "to be brazen-faced." Again, *siècle d'airain* means bronze age. And so on. I admit that in the industrial sense brass is translated by *cuivre jaune*—e.g., *fonderie de cuivre* means brass foundry; or again by *laiton*—e.g., *usine de laiton* means brass works. An object made of brass is colloquially referred to as *cuivre jaune*, or more usually *cuivre*. But in the term bruit d'airain we are not dealing with brass in the industrial or colloquial sense. Rather, it has a figurative or poetical implication. And in French poetry or prose where a brass-like sound is referred to, it is always rendered by *airain*. To take one well-known example in English from the New Testament—(I Corinthians, xiii., 1): "Though I speak with the tongues of men and of angels, and have not charity, I am become as sounding brass, or a tinkling cymbal." This, in the French Testament, runs as follows: "Quand je parlerais les langues des hommes et des anges, si je n'ai pas la charité, je suis un airain qui résonne, ou une cymbale qui retentit." One could give many other examples of this use of *airain*. In English we talk of a "brassy" sound, never of a "bronzy" sound.

Perhaps the confusion between the terms brass and bronze in various languages (in Spanish, for instance, *bronce* means both brass and bronze), lies in the fact that they both refer to alloys of copper, and the distinction between them is not popularly known.

I am, Sir, yours faithfully,
A. I. GRANVILLE MCLAUGHLIN.

St. Thomas's Hospital, S.E., Jan. 4th, 1930.

INFECTION AS A CAUSE OF DIABETES MELLITUS.

To the Editor of THE LANCET.

SIR,—Your annotation on the subject of the ætiology of diabetes mellitus in the issue of Jan. 4th prompts me to relate the following case. I was called to see a child, aged 4, with typical diabetes with a history of wasting, thirst, and polyuria of three months, and of drowsiness for 24 hours, and with urine loaded with sugar and showing a markedly positive ferric chloride test. The weight was 30 lb. 5 oz. Insulin treatment was instituted and during the following 16 days the dosage was increased from 6 units twice a day to 25 units in the morning and 20 units in the evening. At this stage there was a trace of sugar in the urine, the ferric chloride test was negative, and the weight had increased by 3 lb. 7 oz. On the sixteenth day a round worm six inches long was passed, and from this stage until the twenty-eighth day the amount of sugar showed a steady diminution, and the amount of insulin was correspondingly reduced, until at the end of the period the urine was sugar free with no insulin, and the weight had increased by a further 1 lb. 9 oz. At no time was the food reduced, the patient being on a full diet. Subsequently it was necessary to recommence insulin (6 units twice a day), with which treatment the child has remained well, and has continued putting on weight for three months.

The marked recovery which followed the passage of the round worm seems to suggest that the worm had some bearing in the causation of the diabetes, and I should be glad to know your views or those of any of your readers on the subject.

I am, Sir, yours faithfully,
A. T. L. KINGDON, M.R.C.S., L.R.C.P.

Leominster, Jan. 5th, 1930.

PROGRESS IN UROLOGY.

To the Editor of THE LANCET.

SIR,—In his Campbell oration, published in THE LANCET of Dec. 28th, 1929, Prof. A. Fullerton states that radium in the form of emanation seeds applied through the cystoscope is one of the most important and successful methods at our disposal for dealing with tumours of the bladder. I have recently stressed in your columns (1929, ii., 146) the reasons why this is one of the most unscientific methods. Three weeks ago I had to perform suprapubic cystotomy on a woman in order to remove calculi, the nuclei of which were emanation seeds, and also to dissect out a slough of the bladder wall, which contained more seeds. In this patient there still remains the danger of the formation of a vesico-vaginal fistula, owing to destruction of tissue from radium overdosage. The original lesion was stated to be a growth of the base of the bladder, the nature of which I maintain could not be accurately determined without microscopic examination, nor its extent without digital palpation.

I am, Sir, yours faithfully,
A. CLIFFORD MORSON.

Brook-street, Grosvenor-square, W., Jan. 4th, 1930.

IRRADIATED DEXTROCID IN THE TREATMENT OF MALIGNANT TUMOURS.

To the Editor of THE LANCET.

SIR,—I notice in THE LANCET of Jan. 4th a very interesting article on the Treatment of Malignant Tumours with Radium Catgut by Prof. Eugen Joseph, of the University of Berlin. In this article he mentions a compound of iodine and cerium called "Introcid." It may not be commonly known in this country that Prof. Friedrich Voltz, the famous radiologist, working with Geheimrat Prof. Döderlein at the Universitäts-Frauenklinik, Munich, is using in every case a similar preparation called "Dextrocid," containing dextrose, cerium, and iodine. This is obtainable from Hans Portratz, Hamburg, 39, Mülenkamp, 63, in 10 c.cm. ampoules. It is injected into the veins at the bend of the elbow immediately before irradiation by rontgenotherapy with a current of 200 K.V., and 2·5 to 3 M.A., with appropriate thick filter of copper, suitable distance of tube, given skin erythema dosage, and given field. The theory of this injection is that the cancer is sugar hungry, and attracts the dextrose which carries with it the heavy metal cerium and the iodine, and when subjected to deep therapy the molecules and atoms are split up favourably and sensitise the tumour to the X rays. This idea is reminiscent of that put forward by Dr. Monckton Copeman, who advises surface applications and injections in ulcerating growths, of sodium fluorescin, or better, strontium fluorescin, the latter being preferable on account of heavy atomic weight. Cerium is still heavier than strontium. But I have never heard that any of these preparations of cerium or metallic combinations of fluorescin have any effect whatsoever by themselves unless immediately subjected to X rays.

"Radium Catgut," as advised by Dr. Joseph, would appear to be dangerous to surgeon and patient alike, but further experience should prove or disprove its value.—I am, Sir, yours faithfully,

SPENCER MORT, M.D., M.S., F.R.C.S.,
Surgical Director, in Charge of Radium Department,
North Middlesex Hospital, London, N.

Jan. 5th, 1930.

⁂ Early in 1928 we received samples both of "Introcid" and "Dextrocid" from the firm mentioned by Mr. Mort, which apparently deals with both preparations (see THE LANCET, 1928, i., 270).—ED. L.

EMPHYSEMA TREATED BY MECHANO-THERAPY.

To the Editor of THE LANCET.

SIR,—I was much interested in Dr. Harry Campbell's remarks on mechanotherapy in emphysema in THE LANCET of Jan. 4th. In the clinical note which he criticises I could not give full information regarding the raison d'être of the treatment employed. During the first days that I was looking after the patient concerned his condition was too distressed to permit of accurate chest measurements being taken, but the circumference, as soon as it could be ascertained, was 2¼ inches greater than at the close of the treatment; at this time, in addition, the apices were seen to be much less bulging. Dr. Campbell appears to take no account of the improved diaphragmatic movement, which tends to lessen the tense condition of the thorax and give greater facilities for oxygenation. From the clinical point of view I cannot agree that the position of forced inspiration is very good for the patient (although it may be the best state that Nature unaided can bring about). The seriousness of the condition is (as we all know) due to loss of elasticity in the lungs and chest; the treatment I advocate restores this want in greater or lesser degree and this cannot be otherwise than advantageous to the patient. Local manual compression of the chest, especially during an attack of coughing, is most grateful to the patient provided that it is applied elastically and not as a dead weight. The chest wall will not merely have its shape altered, but will also become actually smaller if the rigid costo-chondral joints are rendered mobile, the intercostal muscles more active, and expiration more complete (I have never pretended to restore the quite youthful thorax). Attempts to treat emphysema on the lines given by me have been successfully made since 1865, and more particularly since 1873, when Prof. Gerhardt of Berlin made his first communication on the subject. I have never heard of any bad results where similar methods have been employed, provided that the technique was correct, and I think that there is no danger whatever of "fatal asphyxia" on which Dr. Campbell lays such stress. Perhaps he has not realised that the chest mobilisation as employed by me is a gradual process, each series of compressions lasting about 2–6 seconds, and not a sudden violent one. I am surprised that Dr. Campbell has not found that emphysematous chests become smaller after the patients have performed the expiratory exercises advocated by him over 30 years ago in a book entitled "Respiratory Exercises."

I am, Sir, yours faithfully,
A. KELLGREN-CYRIAX.
Welbeck-street, W., Jan. 5th, 1930.

THE DUMPING GROUND OF NEURASTHENIA.

To the Editor of THE LANCET.

SIR,—May I be allowed to express my appreciation of the Purvis Oration by Sir E. Farquhar Buzzard, published in your issue of Jan. 4th. I have kept records of 307 out-patient psychiatric cases seen at the Western Infirmary, Glasgow, between 1923 and 1926. Of these, 28·5 per cent. were cases in which depression was a leading symptom, without signs of gross organic disease. This figure was made up of: psychoneuroses 13·8 per cent., and manic-depressive psychoses 14·7 per cent.—thus approximating closely to Sir Farquhar Buzzard's figure of a "fifty-fifty proportion" between these two conditions. Now, to the medical man without a psychiatric training, practically all these cases were just examples of "depression" or "neurasthenia," with the term "mental case" as an occasional alternative diagnosis. The point, so very properly stressed in the Purvis Oration, is that these two groups demand an absolutely different mode of treatment; and if the treatment appropriate to a manic-depressive depression is applied to a neurasthenic, or vice versa, the result at best is unsatisfactory, and at worst is disastrous. True neurasthenia is as clean-cut a clinical picture as one is likely to see in psychiatry. That the term has become a dumping ground is the fault not of the general practitioner, but of a system of medical education which expected that the whole of psychiatry—i.e., human nature in its most complex and inaccessible phase—could be taught in ten lectures and ten demonstrations, usually of chronic psychotic patients, to the exclusion of psychoneuroses and early psychoses. Thankfully we observe, with the belated advent of psychiatric clinics in this country, the commencement of a better psychiatric education for medical students. One hopes that the day is not far distant when attendance of students at "psychiatric out-patients" will be compulsory, on the grounds that it is there that the student will see the type of case he will have to deal with in practice—even as this has long been recognised so far as ordinary medical and surgical cases are concerned.

One other aspect of Sir Farquhar Buzzard's oration calls for special appreciation. It is that he attracts attention once more to the importance of clinical psychiatry. One hears so frequently in these days that clinical psychiatry is dead, that we can learn nothing more from it, and that the biochemist is the man who is going to solve all our problems of human nature. Mercifully we have given up the hopeless task of chasing "ideas" from one brain cell to another. Can it be that the ultra-biochemists are, in the words of their equally one-sided opponents, the ultra-psychologists, taking a "flight from reality," from an "intolerable situation," into a "world of phantasy," so rich in hydrogen-ion concentrations, sedimentation velocities, and phospho-proteins, that they forget that the main problem is that of an individual trying to grapple with and adapt himself to his environment, and that the object of psychiatry is to find out why he is not doing it successfully?

Consider what clinical psychiatry was in Clouston's day: a careful, detailed, individualistic record of the patient's life and the stresses which were brought to bear on it; a method of approach which, amplified and extended since first Clouston outlined it, now reaches its mature form in the teachings of Adolf Meyer with his "doctrine of integration" and his "psycho-biological view-point." This doctrine does away once and for all with the old dualistic controversy of body and mind as a necessary part of psychiatric philosophy; and it recognises no incompatibility between functional and organic psychoses, or diseases. It deals only with facts, avoiding the phantastic hypotheses of the extreme biochemists and extreme psychologists, so that by its use we may hope to acquire "a due sense of proportion, and a lively sense of the ridiculous."

I am, Sir, yours faithfully,
IAN SKOTTOWE,
Deputy Medical Superintendent, Cardiff City Mental Hospital.
Jan. 6th, 1930.

MUTILATING OPERATIONS.

To the Editor of THE LANCET.

SIR,—My friend Mr. Hanschell thinks that "some rather obvious data have been overlooked" by me. But I assure him that I have long been familiar with all those so clearly set out by him, and that none seems to me inconsistent with what I wrote. Indeed, I thought my recognition of them was implicit in my phrases. But I am grateful for the opportunity of being explicit, in terms of individual psychology, and of clearing myself from the reproach of being "baffling," even if I acquire that of being banal.

It is of the very essence of individual psychology that "circumstances alter cases," and that, in Adler's words, not only the trauma or the organ-inferiority is of importance, but the courage with which either is met. There may be all the difference in the world between ritual circumcision, done under appropriate conditions, and the boggling "snips," clumsily carried out by house surgeons and others which do, in so many cases, actually "strip the penis," and set up, according to the standards of the unmutilated, a truly villainous deformity. So, in writing that "one is compelled to consider the effect, in provoking racial neurosis, of racial and ritual circumcision" I did not suggest that ritual circumcision *always* provokes racial neurosis—far less that it always does so in the restricted sense in which Mr. Hanschell seems to use the term. I was referring to the desirability of studying the conditions under which it may, or does, produce racial neurosis.

The fact is that such a trauma as a sexual mutilation, and such an organ-inferiority as the state of being without a prepuce may, like any other trauma or inferiority, be met by the individual in any one of several ways. There is, firstly, the strong, or Demosthenes reaction: the effort to overcome that results in a greater development of local function. This is well enough; but sometimes the general, psychical, compensatory process is carried to lengths that are positively anti-social, and in that sense, neurotic. Cruelty may beget cruelty, and the bloodthirsty and sadistic traits of some of the peoples mentioned by Mr. Hanschell are, in this view, psychical over-compensations for the original bloody experience and the consequent deformity. Such psychical over-compensations may be said to have physical analogues in the keloid scars which, as a matter of fact, are so often consequent upon wounds such as those of ritual mutilations, whose infliction has been attended by certain psychological reactions. In the great days of Judah, the predicament of being without a foreskin, whilst a subject of boasting in the presence of the despised Philistines, was, often enough, definitely linked with psychical over-compensations ending in rapings, slaughters and the like. Now the case is altered. The mutilation of which a Maccabæan warrior was proud in moments of victory and bloodshed does not appear in quite the same light to an intelligent, but timid little Jewish boy in an English public school. *His* reaction is of Adler's second type, out of which grow the neuroses and psychoneuroses when his gentile school-fellows compensate for *their* intellectual inferiority by teasing *him* about what they (and he) deem *his* penile inferiority. There is so much difference between being a top-dog and the bottom one! Now, with the utmost admiration for a people among whom I am proud to have many friends, I do ask to what extent the present proclivity of the Jews to general, and not merely sexual, neurosis may not be connected with submission to an organ-mutilation, whilst in a socially inferior position numerically. Of course, the levels at which sexual trauma and sexual organ-inferiority are operative, in the production of neurosis, are subconscious and unconscious as well as conscious ones, and the psychological effects of a sexual trauma or sexual organ-inferiority, which *discourages* the individual, or isolates him to his own disadvantage, spread far beyond the limits of an obviously "sexual" neurosis.

But when ritual circumcision is made the prelude to the assumption of manly rights, the lad, Masai or other, will set his teeth and go through the ordeal pluckily, just as the young rider to hounds, unless he be a coward, will anticipate the blooding he is to undergo when in at his first death. The mutilation is one opening the gates of privilege. But circumcision, as practised in this country by many doctors, under the pretext that it is a safeguard against masturbation, is, in effect, very often a sort of psychological castration, a mutilation that *discourages* the individual, isolating him to his own disadvantage. I appreciate immensely Mr. Geoffrey Keynes's important concurrence.

For centuries untold, I do not doubt, African girls have submitted to *ganza* (the pre-marital rite discussed by the Duchess of Atholl) with courage, nay, even with pride at their initiation into womanhood. But the bride who chooses pre-marital defloration, with scissors "curved on the flat," instead of submission to the bridegroom's "love which thrives on obstacles," is shirking an experience which, if met with courage, is of real value to the individual. The "operation" itself is clearly a concession—and often a willing one—by the "operator" to the demand, already neurotic, for an escape from an occasion for courageous personal effort. Our business, as physicians, seems to be to so guide or arrange that injury and inferiority should be as a stimulus to local and general development without anti-social over-compensation on the one hand, or weakening of independence on the other, and never an excuse for the growth of local and general inferiority-sense. Far less should any injury or inferiority be allowed to become the pretext for Adler's *third* form of reaction—retreat into disease, degeneration, or despair. But, on the other count, we must remember that when social feeling is weakened by the suppression of ritual customs or otherwise, interest in community-life flags, and the race dies out. It is this weakening of the community interest that is so much to be avoided—the Jews, a dispersed people, do so by affirming the family life—and yet the very ritual that serves as a social ligature in one place may entail social disadvantage elsewhere.

Equally, we must hesitate lest, while suppressing tribal customs that may be useful in Africa—just because they are repugnant to our prejudices—we nevertheless open the door, under the pretext of Science, to the practice of similar mutilations under conditions that make for neurosis—just because they satisfy certain demands of the *operator*. I do not think there is any substantial difference between Mr. Hanschell and myself, either in the matter of data, or of opinion. At least, I hope not. But we are what we are by reason of our experiences and our reactions to them. And I am afraid I must charge the blood-shedding and mutilating tendencies of some of the peoples mentioned by him, at any rate in part to the bloody mutilations performed on them, no less confidently than I regard the general neurosis of many weakly men as in great part due to the "unprovoked and unwarrantable trauma" that they have sustained at the hands of doctors.

I am, Sir, yours faithfully,

F. G. CROOKSHANK.

Wimpole-street, W., Jan. 4th, 1930.

TREATMENT OF PERFORATED PEPTIC ULCER.

To the Editor of THE LANCET.

SIR,—The interesting article on Perforated Peptic Ulcer by Mr. Herbert Williams and Mr. C. H. Walsh in THE LANCET of Jan. 4th invites some criticism on account of the rather elaborate technique advocated and the lack of any evidence of a corresponding improvement in the results of the operation. I refer particularly to the perforated duodenal ulcer. Surely the operation for the closure of a perforated duodenal ulcer is usually the simplest task in the whole field of acute abdominal surgery. In the operative treatment of no other acute lesion is Nature so kind and forgiving to the surgeon, and to ignore this, as the authors appear to me to do, is to make the operation unnecessarily severe. The method I have come to adopt for many years past is to close the perforation with a single mattress suture of linen thread, care being taken to pass the needle through the duodenal wall at a judicious distance from the edges of the perforation, and to use a double cast in the first part of the knot so as to prevent any slipping of the suture during completion of the knot. After tying the knot the ends of the suture are left long and a convenient tag of omentum (or even a flap from the falciform ligament) is drawn over the site of the perforation and fixed in position by tying the ends of the suture over it. Rarely is it necessary to do more than this, but if the previous history of the patient, or the appearance of the parts at operation, indicates the existence of manifest pyloric stenosis with gastric dilatation, then (and only then) a gastro-jejunostomy is performed. If the patient's condition is so poor that gastro-jejunostomy would entail a serious addition to the risk, then a high jejunostomy is performed (inserting a No. 10 rubber catheter by the Witzel method) and the stomach is emptied by the passage of a stomach tube before the abdomen is closed. The patient is nourished entirely through the jejunal tube for at least a week, and generally much longer. So far as the treatment of the peritoneal cavity is concerned, as soon as the abdomen has been opened and the diagnosis verified an abdominal swab is placed in the right subphrenic area, another in the right kidney pouch, and one or two in the pelvis; after the closure of the perforation and the wiping of the immediate area these swabs are removed and little, if any, further wiping out of the peritoneum is necessary. Finally, no drainage of the peritoneal cavity is carried out though the parietal wound is usually drained with a wisp of rubber tissue.

In 33 consecutive cases of duodenal perforation treated by me on these lines during the past five years (29 operations at the Manchester Royal Infirmary and 4 at the York Place Nursing Home) there were but two deaths, and neither of these could possibly be attributed to faulty closure of the perforation. One death was due to pulmonary embolism on the 14th day after the patient had been allowed to get up, and the other to acute bronchitis on the 12th day in a man aged 61—the occurrence of bronchitis was amply explained by a total failure, in early February and about nine days after his operation, of the heating arrangements of the large ward in which he was confined. In only one of the 33 was peritoneal drainage instituted, and the only secondary operation required was that of gastro-enterostomy in two cases. The gastric ulcer perforation is treated on similar lines, but here a high jejunostomy, as just described, is regarded as a valuable measure in most cases, in fact as essential in large perforations. In a series of seven such cases there was one death due to reperforation three weeks after operation—probably excited by the fact that the patient was allowed to get up too soon considering the massive size of the perforation at the original operation.

If, then, a mortality-rate of 6 to 7 per cent. in the perforated duodenal ulcer, and one of less than 20 per cent. in the perforated gastric ulcer, can be obtained by such simple methods, one may venture to call in question more elaborate methods, requiring in some instances a specially designed instrument, which produce inferior results.

In closing may I make a plea for the value of the institution of medical treatment of duodenal ulcer as soon as the patient has recovered from the immediate effects of his perforation and operation? The time and occasion are certainly apt, and it is reasonable to believe that the ulcer is particularly susceptible to treatment in this period.

I am, Sir, yours faithfully,

Manchester, Jan. 6th, 1930. H. H. RAYNER.

PSITTACOSIS.

To the Editor of THE LANCET.

SIR,—I note on p. 1320 of THE LANCET, Dec. 21st, 1929, in the annotation on "psittacosis," mention is made of the probability that infection of man from avian sources is exceedingly uncommon, and that the occurrence of this disease amongst birds at the London Zoo is unknown. Whilst in agreement with the former statement I might point out that in 1920, in an investigation of an epidemic amongst birds at the Zoo, the so-called organism *B. psittacosis* was shown by me to be responsible for the infection. Opportunity was also taken in connexion with this investigation to confirm the identity of this organism with the commonest type of *B. aertrycke* associated with human cases of food poisoning. These observations were published in the *British Journal of Experimental Pathology*, Vol. I., No. 3, June, 1920.

I am, Sir, yours faithfully,

H. MARRIAN PERRY.

Public Health Laboratories, Cairo, Dec. 30th, 1929.

TREATMENT OF DRUG ADDICTS IN NEW YORK CITY.

To the Editor of THE LANCET.

SIR,—I was interested in the report of the New York Committee investigating methods of treatment for drug addiction, and in Dr. Stanford Park's comments on it in your last issue. With regard to treatment with narcosan, I can confirm its utter worthlessness from my own experience. Some time ago I treated a case of morphia addiction, stopping all morphia immediately, and giving injections of narcosan every four hours. Up to the time of the first injection there were no symptoms; soon after, intense restlessness set in. After the second injection there was retching and vomiting, while the restlessness had become almost delirium. A third injection producing no improvement, and the condition of the patient rapidly becoming worse, the treatment was abandoned. Incidentally the injections caused considerable local pain and induration which persisted for some days.

I agree with Dr. Park that, in the case of morphia addiction at any rate, gradual withdrawal is the only method of treatment that is either tolerable or tolerated. In the treatment of symptoms that arise I think strychnine, in the form of tinct. nucis. vom., regularly administered, is very valuable, and it does shorten the period required for complete cure.

I am, Sir, yours faithfully,

Edgware, Jan. 5th, 1930. A. G. WESTON, M.D.

The Services.

ROYAL NAVAL MEDICAL SERVICE.

Surg.-Lts. W. Flynn and W. G. O. Fitzpatrick to be Surg. Lt.-Comdrs. Surg. Lt.-Comdr. B. S. Collings is placed on the retd. list.

The following appointments are notified:—Surg.-Comdrs.: V. H. Vey to *Cumberland;* H. Wilks to *Pembroke,* for R.N. Barracks; R. P. Ninnis to *Tiger;* H. M. Whelan to *President;* G. R. McCowen to *Barham;* and G. G. Vickery to *Warspite.* Surg.-Lts.: E. J. K. Weeks to *Centurion;* and R. G. Anthony to *Victory* for R.N. Barracks, Portsmouth; J. Johnston to *Dolphin;* T. S. Osborne to *Victory* for R.N. Barracks; and C. H. Birt to *Glorious.* Surg.-Lts. (D.): H. V. Pell to *Resolution;* and D. L. Simpson to *Assistance.*

ROYAL ARMY MEDICAL CORPS.

TERRITORIAL ARMY.

Lt.-Col. (Bt. Col.) F. G. Lescher from Gen. List, R.A.M.C., to be Col. and to be A.D.M.S., 46th (N. Midland) Div., vice Col. E. A. Wraith.

Capt. A. R. Laurie to be Lt.-Col. and to comd. the 137th (N. Midland) Fd. Amb.

Capts. (Bt. Maj.) G. J. Linklater and A. G. Williams to be Majs.

Lt. D. Lamont to be Capt.

Lt. G. Lyon-Smith (late R.F.A., T.F.), to be Lt.

TERRITORIAL ARMY RESERVE OF OFFICERS.

Lt.-Cols. W. T. Rowe and G. T. Willan, having attained the age limit, retire and retain their rank, with permission to wear the prescribed uniform.

Capt. A. S. Reeves, having attained the age limit, relinquishes his commn. and retains his rank.

ROYAL AIR FORCE.

Flying Officer T. A. Edwards resigns his short service commisson.

Flight Lt. A. W. Comber relinquishes his temporary commission on completion of service.

INDIAN MEDICAL SERVICE.

Capt. S. N. Hayes to be Maj.

Lt.-Col. C. E. Southon retires.

The undermentioned officers have vacated appts. in India:—D.M.S.: Maj.-Gen. Sir W. H. Ogilvie, I.M.S. D.D.M.S.: Col. W. R. Blackwell. A.D.M.S. (Pers.): Lt.-Col. A. A. C. McNeill, I.M.S. D.A.D.M.S.: Maj. (Bt. Lt.-Col.) E. T. Potts, R.A.M.C.

The undermentioned appointments have been made in India:—D.D.M.S. and D. (Hosp. Orgn.): Lt.-Col. (Bt. Col.) E. A. Walker, I.M.S. A.D.M.S. (Pers.): Maj. (Bt. Lt.-Col.) E. T. Potts, R.A.M.C. D.A.D.M.S.: Maj. H. H. Brown, I.M.S. Dir. Med. Orgn. for War: Lt.-Col. A. A. C. McNeill, I.M.S.

ORDER OF THE HOSPITAL OF ST. JOHN OF JERUSALEM.—The following appointments in the Venerable Order have been sanctioned by the King: *Commanders:* Dr. C. Bage, Lieut.-Colonel H. R. G. Poate, Dr. L. W. Dryland, Dr. N. C. Fletcher, and Dr. G. P. Mosscrop. *Officers:* Mr. H. L. Brownlow, Dr. F. Hichens, Major R. D. O. Cran, Lieut.-Colonel A. R. Falconer, Sir Louis E. Barnett, Dr. J. B. Gunson, Dr. G. H. Hogg, Dr. J. H. G. Robertson, Dr. A. N. McKelvey, Lieut.-Colonel H. Spackman, Colonel A. V. Clarke, Dr. Daisy E. Platts-Mills, and Dr. Elizabeth G. Stuart. *Serving Brothers:* Dr. A. P. Gibbons, Dr. A. B. Cardew, Dr. C. Hibbert, Dr. J. Murray, Dr. J. W. Wyncoll, and Dr. J. L. Callaghan.

Medical News.

SOCIETY OF APOTHECARIES OF LONDON.—The annual Yeomanry Dinner of this Society was held at the Apothecaries Hall on Tuesday, Jan. 7th, when the Master, Lieut.-Colonel. C. T. Samman, presided over a large company which included thirteen Masters or Past Masters of City Companies, with the Minister of Health, Mr. Arthur Greenwood, as the principal guest. After the loyal toasts, the Master proposed the health of His Majesty's Ministers in a short speech in which he claimed, and gave evidence for his claim, a place in the national progress for the Apothecaries. Over 250 years ago, he said, they were acknowledged to have rendered splendid service to the population of London during the devastating plague, and now, within the last few weeks, the Society had provided the machinery, through an honours diploma, for improving the obstetric service of the country. In associating the name of Mr. Greenwood with the toast he paid a high tribute to the work of the Ministry of Health during its ten years of life.

Mr. Greenwood, in response, disclaimed any intention of providing statistical information, but pointed to certain significant figures, proving great progress in general and domestic hygiene, a circumstance which, he said, must not blind them to the fact that the nation still has a lamentable mass of disability to deal with. He pointed out that public health was a world problem, which could only be solved by the coöperative work of the medical profession in all countries; and not only of the members of the medical profession, but of members of the public, plain ordinary folk like himself, who wished to understand the proper way of living in order to promote the general welfare. He professed his profound belief in the fundamental soundness of our people, obscured though it was in many directions by social evils; our people, he added, were leading the world still in the devising and carrying out of public health measures, while they had been the predominant force in the health section of the League of Nations.

Sir George Buchanan, the senior warden of the Society, in proposing the health of the guests, pointed out to the high officers in City Companies, who were present, the peculiar position which the Society occupied as the exponent of "a mystery," and he suggested that King James I. from whom their Charter was derived, had been responsible for the phrasing of his document. Mr. Justice Humphreys, Sir Andrew Balfour, and Sir Humphry Rolleston responded.

HUNTERIAN SOCIETY.—The banquet to commemorate the 202nd anniversary of the birth of John Hunter will be held at the May Fair Hotel, Berkeley-street, London, W. 1, on Thursday, Feb. 13th.

GENERAL COUNCIL OF MEDICAL EDUCATION AND REGISTRATION.—A new cycle of inspection of final examinations in medicine, surgery, and midwifery is about to commence, and under Section 3 (2) of the Medical Act, 1886, the following inspectors have been appointed: In medicine, Dr. T. Wardrop Griffith; in surgery, Dr. Farquhar Macrae; and in midwifery, Dr. J. S. Fairbairn.

BRITISH SOCIAL HYGIENE COUNCIL.—A course of 10 free lectures will be given under the auspices of the British Social Hygiene Council at the Central Hall, Westminster, London, S.W., on Thursdays beginning on Jan. 23rd at 5.30 P.M. and ending on March 27th. The general title of the lectures "Some Practical Aspects of Social Hygiene with Special Application to Problems of Youth" indicates their scope. On Jan. 23rd and 30th Mr. C. C. Hentschel will discuss the training of youth and the influences of heredity and environment upon individual development. On Feb. 6th Dr. I. Feldman will lecture on continence in its physiological bearings, and on Feb. 13th on general problems of adolescence. On Feb. 20th Dr. Marjorie Smith Wilson will deal with the medical aspects of social hygiene; and on Feb. 27th and March 6th respectively Prof. Cyril Burt will lecture on the psychology of the child and the adult. On March 13th Dr. Sloan Chesser will lecture on social ideals as expressed in the home and domestic health; and on March 20th Mrs. Neville Rolfe will discuss social hygiene from the community point of view. On March 27th there will be a general discussion under the chairmanship of Prof. Winifred Cullis, head of the Department of Physiology at the London School of Medicine for Women, in which all are invited to participate.

These lectures were recently announced for delivery at the Livingstone Hall, but the great number of applications for tickets necessitated the holding of the meetings at the Central Hall, Westminster, with its greater accommodation

NATIONAL BIRTHDAY TRUST FUND.—This Fund, which has for its object the extension of maternity services, recently held its annual meeting. It was reported that only 720 beds are available for its purposes in the voluntary hospitals, and that Lord Melchett's statement in a recent speech that there are 2000 beds empty in hospitals referred to poor-law infirmaries. Owners of famous houses are being asked to give tea-parties to view them for the benefit of the Fund.

ROYAL PORTSMOUTH HOSPITAL.—An anonymous benefactor, who is now stated to be Sir Woolmer White, a former chairman of the Governors, recently offered to give £40,000 towards enlargement and modernisation of this hospital. The condition was annexed that the city should raise an equal amount. It is now announced that the condition has been fulfilled, and that the entire sum of £80,000 is available for the remodelling of the hospital.

ROYAL SANITARY INSTITUTE.—The Henry Saxon Snell Prize was founded to encourage improvements in the construction or adaptation of sanitary appliances. It will be awarded in 1930 for an essay of not more than 5000 words on Improvements in the Sanitary Provisions of Schools. The prize will consist of 50 guineas and a medal. Further particulars may be had from the secretary of the institute, 90, Buckingham Palace-road, London, S.W. 1.

METROPOLITAN HOSPITAL SUNDAY FUND.—At the annual meeting of the Metropolitan Hospital Sunday Fund it was stated that the collection for 1929 (£85,200) again showed a small reduction—£214. The £35,400 from church collections was an increase of only £3700 over the amounts coming from those sources in 1885. In the hope of reaching people who do not go to church, 200 collecting boxes, shaped like golf balls, were distributed among clubs, but the result was an average of not more than £1 per box.

BRITISH INSTITUTE OF PHILOSOPHICAL STUDIES.—At 8.15 P.M. on Tuesday, Jan. 14th, at the Royal Society of Arts, John-street, Adelphi, London, W.C. 2, Principal L. P. Jacks will lecture on Adult Education. This lecture will be open to the public without charge. Four lectures on Science and Art will be given by Prof. S. Alexander at 5.45 P.M. on Fridays, Jan. 31st, and Feb. 7th, 14th, and 21st. At the same hour on Thursdays, Jan. 16th, 23rd, 30th, and Feb. 6th, 13th, 20th, Prof. W. G. de Burgh will give six lectures on Some Aspects of the Moral Life. Both courses of lectures will be given at the Royal Anthropological Institute, 52, Upper Bedford-place, London, W.C. Syllabuses and form of registration may be had from the Director of Studies, 88, Kingsway. W.C. 2.

THE NEW PENSIONS ACT.—The Widows', Orphans' and Old Age Contributory Pensions Act, 1929, which came into operation on Jan. 2nd, brings in two large groups of new pensioners. The first group consists of wives of men who reached the age of 70 before Jan. 2nd, 1928, and are entitled to full pensions under the Old Age Pensions Acts of 1908 to 1924, free from the conditions as to means imposed by those Acts, by virtue of their insurance. The wives of these men have hitherto had to wait until they also reached age 70 before being given old age pensions in right of their husbands' insurance. Under the new Act these women are now to be entitled to old age pensions between the ages of 65 and 70. Claims under this heading should be made on Form C.P.1, which can be got at any post-office.

The second group of new pensioners are widows of men who died (or attained age 70) before Jan. 4th, 1926. They are to receive widows' pensions at the age of 55. The essential condition for the award of these pensions is that the claimant's husband must have been of the insurable class at some time within the three years before his death or his 70th birthday. The precise terms of this and other conditions are set out in an explanatory leaflet (W.P.5) which can be had on application at any post-office. For qualified widows who will have reached the age of 60 before Jan. 1st, 1931, the new pensions are to begin from July 2nd, 1930, or the date of attaining age 60, whichever is the later; in all other cases the pension will begin from Jan. 1st, 1931, or the date of attaining age 55, whichever is the later.

The leaflet now available at post-offices explaining the new pensions also gives full particulars of the changes made by the Act in existing conditions. Provision is made enabling persons who go to any part of the Empire to continue receiving their pensions or to maintain their insurance for pensions purposes. The right to become voluntary contributors for all health insurance and pensions benefits is now given to persons in excepted employments who are compulsorily insured for some or all pensions. A memorandum dealing with voluntary insurance may be had from the Ministry of Health, Whitehall, S.W. 1.

medical or surgical treatment. There he can be sure of the highest skill available, and of everything in the way of equipment that modern knowledge and ingenuity have devised. Once he is safely in bed in a ward in any one of our voluntary hospitals, docker or dustman can count on receiving treatment at least equal to that which prince or millionaire can command. The results being what they are it is truly astonishing that the electors have for so long allowed their political representatives to trifle with the question of adequate hospital provision. It is stated that there is, at this moment, a waiting list of 5000 seeking admission to the Royal Edinburgh Infirmary alone.

Club Practice.

Since the middle of the last century, when parish doctors were appointed in every district to provide domiciliary treatment under the poor-law for those unable to make any medical provision for themselves, there has been a steadily increasing recognition of the desirability—on public, philanthropic, and prudential grounds—of arranging for some sort of medical supervision and treatment in times of stress. Parish doctoring was, for the most part, not such as to lead those not so compelled to trust themselves to its ministrations. Throughout the country a system of voluntary clubs grew up, the members of which, by paying a few pence a week, were guaranteed, in addition to sundry money payments during illness or old age, the services of a doctor when necessary. These club doctors received but a small annual payment in respect of each member—generally about four shillings, out of which drugs had to be provided—and, although many gave a service fully up to the standard represented by contemporary medical knowledge, the system put too great a strain on professional and technical honour. Club doctoring came to be looked upon as but one shade better than parish doctoring, and accordingly the political ground at the end of the first decade of this century seemed ready for some big national scheme of domiciliary treatment—a readiness which Mr. Lloyd George and other astute, public-spirited or philanthropic politicians sought to exploit.

National Health Insurance.

Thus it was that, in 1912, the Health Insurance Act came into operation and every wage-earner in the country was provided with a panel doctor of his own. Unfortunately, the methods of politics, rather than those of science or of statesmanship, were the ones employed in bringing about this medical revolution. In practice politics all too often involve the squaring of vested interests. Mr. Lloyd George was faced by powerful corporations whose goodwill, or at least compliance, was essential to the enactment and carrying out of his proposals. The big Friendly Societies and the industrial Insurance Companies were quieted by being given the control and administration of the various cash benefits to be provided. The doctors, seeing the danger which confronted that independence of judgment and that personal relation between them and their patients on which the best practice has always been based, were up in arms. But they also proved susceptible to financial promises. Consequently, in the discussions and the bargainings between the Government and the medical profession, it was rate of payment rather than efficiency of service that always stood first on the agenda.

The Defects of the Panel System.

The one piece of medical organisation that emerged is what we are now familiar with as the panel system; the working of which has at least been an interesting experiment in democratic methods. Considered in the large, the panel service represents a great advance on any collectively provided medical service that preceded it. Moreover, anyone familiar with the conditions of private medical practice among the city poor at the beginning of the present century can but recognise the immensity of the improvement that has taken place. The doctor—so far as insured persons are concerned—is spared the humiliating experience of taking from an ill-nourished family a fee which represents to-morrow's dinner; nor need he apologise for visiting his pneumonia patient as often as he thinks it desirable. Personally, I have always felt that it would be a good thing were the private and individual acceptance of medical fees made a penal offence, like the acceptance of secret commissions: but perhaps I am a little biased in this matter. Still, I think that plenty of other doctors with similar experience of industrial practice in pre-insurance days will feel much as I do.

It was, I believe, the original intention of Mr. Lloyd George and his advisers to establish throughout the country a salaried service of district insurance doctors, and many people regret that the original intention was not carried out. Many arguments may be advanced on either side, the force of which varies with the point of view. It is, of course, desirable, in the interests of national health, that conscientious doctors shall be free to act according to their own judgment, regardless of the whimsies, prejudices, and misconceptions of ill-informed patients. Under the panel system, which makes the doctor's income depend mainly on his popularity, a certain measure of scientific independence is inevitably sacrificed. But, if we regard the prime function of the panel service as the providing of a "benefit" for the individual patient—the sort of service he would normally provide for himself if he had the money—then, in the present state of popular education, it is far better for the insured person to be in a position to express his dissatisfaction by "changing his doctor" just as a private patient can and does, than to have no remedy except that of making a formal complaint to some committee or administrative officer. Though good and conscientious doctors do their best work when least interfered with, such men do good work under any scheme. The panel system has materially raised the standard of medical treatment in poor areas, and it has drawn to those districts hundreds of fairly competent young practitioners who, in the old days, would never have thought of facing the discomforts involved for the small fees then obtainable. But, in the course of raising the general standard of industrial medical treatment, it has tended to discourage originality and to formalise the relation between doctor and patient. These evils are, however, not essential accompaniments of the system. Their existence may, in fact, be more accurately attributed to the self-assertiveness and spiritual pettiness of a bureaucracy—lay and medical—that is more and more firmly establishing itself. Unless this is changed we may increasingly expect to find that men of character and independence will avoid the panel service, which will attract mainly those susceptible to the bait of a fairly good assured income for uninspired routine work.

A vicious circle has been established. Suavity appeals to the average patient no less than skill; a mere formal observance of the regulations satisfies the authorities and paymasters; outstanding excellence wins neither praise nor reward in either quarter. Originality and devotion, as things are at present, are as likely as neglect or incapacity to bring the practitioner before some or other tribunal entitled to demand an explanation of his eccentricity.

The Remedy.

But these extraneous defects could readily be removed if the great body of medical practitioners were as concerned with technical efficiency and professional honour as with the Insurance Committee's quarterly cheques. And the same is true of those limitations, artificial and illogical to a degree, which go far to sterilise medical work under the Health Insurance Act. What can be said of a national system which, whilst providing some kind of medical service for those employed members of a family who are over the age of 16 years, leaves the rest of the household to get along the best way they can; which puts "out of benefit" a married woman who devotes herself to her home and children; and which furnishes only such medical treatment as even poor people can most easily obtain for themselves—viz., such as can be given by "a general practitioner of average competence and skill?" In actual practice this "treatment" works out at the annual prescribing and provision of millions of gallons of "medicine," probably not more than one-tenth of which has the slightest therapeutic significance. "He is the best doctor who knows the worthlessness of the most drugs." Treatment is more and more demanding specialist knowledge and elaborate equipment, and these should be available promptly and conveniently to all those who really need them.

The enormous fall in the death-rate that has characterised the last half century is due hardly at all to strictly "medical treatment" in the old sense of the term. Mainly the credit belongs to our effective sanitary service, to aseptic surgery, to sounder hygienic notions, and to an improvement in the general standard of living. In spite of its enormous possibilities, it is difficult to place high valuation on the part in the promotion of the national health played by the Health Insurance Act, as at present administered and medically interpreted. Either the panel system should be abolished, or the whole population—at any rate the whole working-class population—should be brought under it. Apart from the treatment of minor ailments calling for no particular specialist skill and no particular equipment, and the directing of the domiciliary treatment of such illnesses as call for little beyond nursing and symptomatic drug therapy, the panel doctor might most usefully be employed in the work of preliminary diagnosis and of hygienic education. For the first of these duties he is already moderately well trained; for the second he is hardly trained at all. If we are to produce a really effective health organisation the General Medical Council will have to examine in a revolutionary spirit the whole system of medical education in this country

The Future.

Since the establishment of the Ministry of Health something has been done in the way of coördination. But the

Ministry has far too many and too mixed duties and interests. The whole problem needs to be considered from the point of view of national requirements; free from the dominance of parsimony, local or sectional jealousies, or vested interests. Between the several units which make up the medical army there is little cohesion, little inter-relation. Nor, in spite of the unctuousness and fine sentiments which characterise so many medical utterances, is there as yet any widespread desire among practitioners to subordinate temporary and personal advantages to the well-being of the nation or to the perfecting of the service of which our guild is the privileged instrument.

PUBLIC HEALTH IN KENYA.

A GOVERNMENT report for 1928 on the Colony and Protectorate of Kenya has just been issued. Referring to public health it states that the most outstanding feature of the year with regard to the incidence of communicable disease was the occurrence of a number of severe outbreaks of malaria in certain parts of the highlands of the colony. In all six districts were affected, four being native reserves and two being European farming areas, or "settled districts." The latter had been affected to some extent by the epidemic of 1926, while the four native reserves, so far as is known, had not previously suffered from malaria in epidemic form. In 1926 the most serious incidence occurred in the central highlands, but in 1928 the latter were not seriously affected, the incidence of epidemic malaria being confined to the north-western highlands—that is, to the more or less continuous stretch which lies to the north-west of the Great Rift Valley and between the valley and the basin of the Victoria Nyanza. The position for a time was undoubtedly serious. It is a matter for some satisfaction, however, that there is now an increased appreciation of the fact that under present conditions malaria, even in non-endemic areas, may from time to time become of grave importance. No other unusual incidence of communicable disease occurred during the year, and it cannot be said that the general health of the population of the colony as a whole was less satisfactory than in previous years. In the absence of accurate vital statistics it is impossible to measure any small variations in the general standard of health which may be occurring.

But work was carried out during 1928 which at a later date will allow of more accurate estimates being made of the results of the medical, sanitary, agricultural, and social developments which are now taking place in the native reserves. This work was undertaken more particularly in connexion with the ankylostomiasis campaign which was carried out in the Digo Reserve on the coast, where large numbers of the natives who presented themselves for treatment were submitted to a full and careful physical examination and the results recorded. The findings confirm the opinion which has been expressed in many previous reports to the effect that the standard of health which prevails among African natives is generally at a low level, and that, with few exceptions, the physique and capacity of the population are affected as the result of infection with those endemic preventable diseases which generally prevail where the standard of culture of the people and the cultivation of the land is still primitive. In the reserves other than Digo the collection of information regarding the physical and pathological condition of the inhabitants has also been pursued. Of the general observations which have been made, perhaps the most outstanding have reference to the incidence of infection with intestinal worms and the effect of such infections on the population. Hitherto, among the diseases resulting from infection with intestinal worms, hookworm alone has received much attention, but during the past year evidence has been accumulating which indicates that the disability which results from infection with tapeworms and roundworms is by no means negligible, and that in countries such as Kenya, where the infections are common, the diseases which result play a much larger part in lowering the standard of the public health than has hitherto been realised. In the Teita Reserve, in Ukamba Province, a sanitation campaign was carried out, the infection with which it was hoped to deal being roundworm.

During the year the incidence of plague was not notable and was chiefly limited to a small outbreak in Nairobi and sporadic outbreaks in the endemic areas of the Nyanza Province. In the settled areas the incidence was very low. Four sporadic cases occurred in Mombasa. Throughout the year five cases of small-pox were reported, but in no case could the source of infection be traced. Of the acute fevers, pneumonia, as usual, caused much sickness, and in the towns especially, and among the poorer section of the urban native population this disease was responsible for a high mortality. In the native reserves yaws, in spite of the large number of cases which have been treated during recent years, continues to cause much disability, and it is only in the Kikuyu district of Fort Hall that there would yet appear to have been a large reduction of the incidence. The total number of cases treated in 1928 was 85,617. In certain parts of the Nyanza Province the incidence of syphilis presents a problem of some magnitude, and during the year increased efforts have been made in these areas to induce patients to attend regularly for treatment. These efforts have met with some degree of success, but the number of patients so attending is still small in proportion to the numbers who do not return after they have been relieved of their more distressing symptoms.

The work of the medical department during the year was carried out on normal lines, except that in certain native reserves particular attention was devoted to helminthic diseases and the treatment of syphilis, while in the towns particular attention was given to the control of malaria. The investigation of mosquito conditions received special attention. The general health of native labourers may be confidently said to be steadily improving. This is due in part to the progressive realisation by employers of the importance of an adequate and varied diet and of sanitary surroundings, and partly to the regular system of Government inspection and exhortation which is maintained by the principal labour inspector and his officers.

The range of temperature between different parts of Kenya is very wide. At Lamu on the coast the mean shade temperature is 80° F.; at Mombasa it is 77° F.; in Kisumu, on the Victoria Nyanza, it is 72·5° F.; and in the Rift Valley and highland areas is normally between 58° F. and 65° F. The rainfall is generally well distributed. Recipitation varies considerably with the physical configuration of the colony. The average annual rainfall, taken over a number of years, ranges from 10 inches at Athi River, on the plains some 20 miles south-east of Nairobi, to 86 inches at Songhor in the Nandi Hills east of the Victoria Nyanza. The low-lying districts on the northern frontier are dry. The heaviest rainfall is normally experienced from March to June, and October to December. Hail is of comparatively rare occurrence, and is confined to restricted belts. Frost does not occur below 8000 feet except in some damp hollows. The land area is 219,731 square miles, and the water area 5229 square miles, the latter including the larger portion of Lake Rudolf and the eastern waters of the Victoria Nyanza, including the Kavirondo Gulf. Mount Kenya, after which the colony is named, is 17,040 feet in height and is capped by perpetual snow and ice. Mount Elgon, also an extinct volcano, is 14,140 feet in height and is slightly below the level of perpetual snow. The Aberdare Range contains Settima (13,000 feet) and Mount Kinangop (12,816 feet). The Mau Escarpment attains a height of over 10,000 feet. The total population of Kenya is now estimated at 2,891,691. By a census taken in 1926 it was shown that there were then included 12,529 Europeans, 30,583 Asiatics, and 10,557 Arabs. The number of Africans, by a rough calculation, is put at 2,838,022.

CARDIAC IRREGULARITY AND THYROID TOXÆMIA.

IN a discussion of the cardiac irregularities associated with hyperthyroidism S. W. Wishart[1] has just described a case, which is one of six similar cases he has observed, in which paroxysmal auricular fibrillation proved to be the earliest sign of hyperthyroidism. The case described was that of a girl, aged 28, who during one year had six attacks of fibrillation at irregular intervals, the maximal duration being two days. In five of these an electrocardiographic examination was made, and this showed fibrillation with a rapid ventricular rate. On none of these occasions was there any clinical evidence of hyperthyroidism, and the basal metabolic rate was within the limits of normal on repeated estimation. At the end of one year this patient developed clinical signs of early Graves's disease, a sinus tachycardia of 110, and a basal metabolic rate of plus 40 per cent. Thyroidectomy was performed, and the gland showed the typical histological picture of Graves's disease. During the year following operation her health was excellent and there was no return of fibrillation. Wishart considers that auricular fibrillation and flutter are the irregularities most frequently met with in hyperthyroid conditions, and that these may be the earliest detectable signs of thyroid toxæmia. He argues that because removal of the thyroid causes an apparently complete recovery in the paroxysmal types, the changes in the heart muscle must be transient. This view is supported by the absence of subsequent cardiac enlargement or changes in the T-wave or the development of signs of cardiac failure.

AN EXPERIMENT IN CHILD GUIDANCE.

In the course of a recent discussion on the difficult child, reported in THE LANCET of Dec. 14th last (p. 1261), some speakers hinted that the pædiatrist was too often forgotten when psychiatrists, psychologists, and social workers set about the task of helping maladapted children. The Children's Clinic at 85 Clarendon-road, W.1, is an attempt to approach the problem from the pædiatrist's point of view. A fundamental belief underlying the work of the clinic is that physical and mental conditions are invariably associated, and there is a biochemical department to study the correlations between biochemical findings and nervous conditions. Another development of this belief is the gymnastic department; every child takes part in rhythmic exercises and free movements in order to give full value to the correlation between posture and habitual physical actions on the one hand and temperament and mental outlook on the other. On the psychological side the clinic has methods of its own which are not described in the report, beyond the rather vague statement that by special kinds of play the children are allowed and encouraged to work out their own problems and bring their difficulties to light. The situation is then explained as far as possible to the child, the parent, and the school teacher. As every child psychologist knows the parents are often the cause of the trouble, and the parent's department at this clinic is doing what it can to correct faulty adult attitudes. The mother is also taught what diet and hygiene is necessary to build up the child's physical health. There is a mother's room where mothers sit while they are waiting for their children, and where they form a club to discuss the virtues and vices of cinemas, the proper bedtime for small people, and such-like matters. At present the clinic is open only on two afternoons in the week and its work has to go on in rented rooms. Fifty-five children have been seen during the first year and there is a waiting list. The work is admittedly in an experimental stage but the experiment is worthy of a fair trial. For this a house is almost essential, and the report is issued with an urgent appeal for funds to equip this house and to provide proper remuneration for the staff.

AN INDIAN NATIONAL SCRIPT.

Dr. A. Latifi, LL.D., has written a brochure advocating a national script for India and the paper has been circulated by the East India Association. There is no doubt that the replacing in India of what the author calls a "jungle of scripts" is a pressing matter, for educational training is limited by the confusion, which has also the unfortunate result of limiting the number of European scholars who make personal research into Indian science. Dr. Latifi points out that there are three linguistic candidates for the provision of a national Indian alphabet, the Arabic, the Devanagri, and the Roman, and he finds the superiority of the Roman obvious. The Arabic script has, he reminds us, been tried and found wanting, while as between the Devanagri and the Roman the significant remark is made that Devanagri can in many respects be regarded as identical with Sanskrit, while Sanskrit can be intelligibly rendered into Roman. The details of a reformed script on the Roman pattern would naturally be left to the settlement of an expert committee, but for the use of those interested, as well as of such a committee, Dr. Latifi submits a scheme of his proposed translation into Roman Urdu.

A SURVEY OF BLINDNESS.

FOR the past four years the Colorado Commission for the Blind have been attempting to collect accurate information about the amount of blindness within the State. The result of their study together with the analysis of 150 private cases is reported by Dr. Edward Jackson,[1] of Denver. The 1053 cases reported to the Commission do not afford a complete record of blindness in the State, for all of the blind do not seek assistance, but their analysis is of unusual value inasmuch as the great majority of these cases have been examined for the commission by a specialist. All who do not conform to the standard of blindness—less than 1/10 vision in the better eye—have been excluded from the analysis. Cataract was the most important single cause (460 cases). Most of the cataracts were "senile." Opacities of the cornea were next in frequency (157 cases), this being the chief cause of blindness in 49 cases arising from trachoma. In 151 cases blindness was attributed to lesions of the retina and choroid, recognised by ophthalmoscopic examination. Atrophy of the optic nerve (132) was due certainly in 22 cases and probably in many more to syphilis. In three cases it came from drinking wood alcohol, and in others probably, it is said, from alcoholism and tobacco. There were 97 cases of glaucoma not sufficiently advanced to be classified under optic atrophy. Injury was the cause of blindness in 66 cases, high myopia clearly the cause in 43 cases, and probably in others. Dr. Jackson concludes that the majority of eyes that become blind could have been kept with some sight by early proper treatment. The prevention of blindness, he says, depends on (1) securing good treatment at the earliest possible time; (2) ability of physicians to diagnose disease that may lead to blindness when the eyes themselves seem to be little if at all affected; (3) the understanding that diseases which do not usually affect the eye may in some cases cause blindness and need to be watched with this in mind; and (4) the ability of oculists to recognise dangerous conditions and their willingness to make decisions and to operate when blindness can only be prevented by prompt medical intervention.

T.C.P.

A PREPARATION whose full style is Trichlorophenylmethyliodosalicyl has been put on the market by British Alkaloids, Limited, 104, Winchester House, London, E.C., as a general antiseptic and germicide, while there is evidence that as an electrolyte it has proved of value in the treatment by ionization of cases of arthritis. The preparation is testified to by many members of the medical profession as being non-toxic and analgesic, and a useful application as gargle or spray in affections of the nose and throat, and as a lotion in wounds and scalds as well as in eczema, chilblains, and hæmorrhoids.

A UNIVERSITY IN THE CAUCASUS.

To the Editor of THE LANCET.

SIR,—On Jan. 12th, 1930, the Baku (now Azerbaidjan) State University will celebrate its first jubilee. Born in the throes of civil war after the break-up of the old régime in Russia, this University has, during its 10 years of existence, become so bound up with the general and national culture of the country that Azerbaidjan can hardly be imagined without it. It opened with three courses in the medical faculty and the very beginnings of a philological faculty. Now there are the faculties of medicine, jurisprudence, and pedagogy; there are 2300 students, and the University has already given 1300 doctors to the Republic. The teaching in the faculty of pedagogy is in Turkish, whilst in the other faculties it is in Russian. The great majority of the scientific workers belong to the native population.

The nucleus of the University was a small group of professors, chiefly from the faculty of medicine (V. S. Razoumoffsky, I. I. Shirokogoroff, A.A. Oschmann, A. M. Levin) and from the former philological faculty, who, with part of the students from the medical faculty left, for objective reasons, the Transcaucasian University at Tiflis, in the full assurance that in Azerbaidjan they would find the best conditions for a continuance of their work. The prognosis was correct; at present the University is not only the cultural centre of Azerbaidjan, but is becoming a centre for the whole Union of Soviet Republics. In the not distant future it will be without doubt the vanguard of culture in the neighbouring countries of the East.

I am, Sir, yours faithfully,

I. SHIROKOGOROFF,
Professor of Morbid Anatomy.

Jan. 1st, 1930.

OCCIDENTAL MEDICAL BOOKS TRANSLATED INTO CHINESE.

Dr. Thomas Gillison is returning to China shortly at the age of 70, to continue his translation into Chinese of medical text-books. He is already responsible for the translation of Cunningham's Practical Anatomy, Luff's Chemistry, and Mitchell Bruce's Materia Medica. Dr. Gillison was from 1883 to 1918 principal of the London Missionary Society's Hospital at Hankow, and then joined the staff of the Shantung Christian College Medical School, one of the chief medical training centres in the East. In 1923 he returned to Hankow where he continued to work until his retirement last year. He holds the Chinese Order of the Excellent Crop.

Erratum.—In the list of New Year Honours published in THE LANCET last week the order conferred on Surgeon Rear-Admiral Robert William Basil Hall should have been recorded as the C.B. (Military Division).

MANCHESTER YEARLY INQUESTS.—The number of deaths reported to the Manchester City coroner during 1929 was 1368. Inquests were held in 452 cases. Motor fatalities amounted to 105, or 20 more than in the previous year. In Salford last year 219 coroners' inquests were held, and the largest number of them—42—concerned street accidents.

An Analysis
OF
POST-OPERATIVE PULMONARY COMPLICATIONS.

BASED ON CASES AT UNIVERSITY COLLEGE HOSPITAL, LONDON, IN ONE YEAR.

BY C. J. FULLER, D.M. OXF., M.R.C.P. LOND.,
PHYSICIAN TO THE ROYAL DEVON AND EXETER HOSPITAL: LATE MEDICAL REGISTRAR AT UNIVERSITY COLLEGE HOSPITAL.

THE series here presented was collected from the surgical wards of University College Hospital during 1927. As resident medical officer and later as medical registrar during that period I had unusual opportunities of examining the majority of the cases personally and thus avoiding the difficulties that arise in classifying observations made by others.

The total number of patients operated on during the year was 1478. The post-operative lung complications noted during that period are classified under the following headings:—

	Cases.
1. Bronchitis	24
2. Lobar pneumonia..	2
3. Broncho-pneumonia	75
4. Broncho-pneumonia with empyema	1
5. Broncho-pneumonia followed by infarction of the lung	1
6. Abscess of the lung	4
7. Massive collapse	8
8. Infarction of the lung	9
Total	124

I have, as far as possible, excluded chest complications which were not directly due to the operative procedure and which would have developed whether an operation was performed or not, as, for example, in cases of osteomyelitis.

In order that there shall be no ambiguity as to the above classification, I propose to give a brief description of each form of complication, illustrated by typical examples taken from the present series.

BRONCHITIS.

This type of post-operative chest complication is closely associated with the broncho-pneumonic group, the more severe cases of bronchitis merging directly into the milder types of pneumonia. It is, therefore, difficult to draw any distinction between the two groups; consequently I have included any cases in which consolidation was doubtful under the present heading.

There were 24 cases, a number that is probably lower than it should be owing to the fact that some of the minor cases escaped notice. The onset was commonly during the first two days after operation. It was accompanied by persistent coughing or a desire to do so. The sputum was at first scanty, but after 24 to 48 hours was expectorated in moderately large quantity. It was muco-purulent in the majority of cases and the presence of blood was unusual. The physical signs consisted of scattered rhonchi throughout both lungs with a slight impairment of percussion note at the lung bases in a few cases.

Of the 24 cases, 20 occurred after abdominal operations, 2 following the removal of a growth from the pharynx and 1 after each of the following: thyroidectomy and nephrolithotomy. There was one death in this group—namely, after removal of a pharyngeal carcinoma (4·1 per cent. mortality). A necropsy was not allowed.

CASE 1.—A man, aged 46, admitted on July 2nd with a duodenal ulcer which had perforated four hours previously. The ulcer was oversewn and a gastro-jejunostomy performed. The anæsthetic was ether, given by the open method. The patient had a slight temperature on the day of operation and a few scattered rhonchi in his lungs. On the first day after operation the temperature was further raised and was maximal on the second at 101·5° F., the respirations being at the rate of 40 per minute. The physical signs were impaired resonance over an area at the upper part of the right lower lobe and scattered rhonchi throughout both lungs. The sputum was muco-purulent, but contained no blood. The temperature returned to normal on the fifth day and the patient made an otherwise uneventful recovery.

LOBAR PNEUMONIA.

This group differed from the next and largest one, the broncho-pneumonias, in many ways. There were two cases and the disease was in both severe in character and led to a rapidly fatal termination. The physical signs were those of a massive rather than a patchy consolidation. The sputum was copious and rusty in colour. It is worthy of note that at the time these cases occurred there was an epidemic of mild influenza in the wards and the one in which they were was closed soon afterwards on that account. Whether these two cases were instances of true influenzal pneumonia or of lobar pneumonia I am uncertain. They were, however, definitely in a different category from the broncho-pneumonic group. The following description is of one in which a necropsy was obtained.

CASE 2.—A man, aged 65, admitted on Jan. 19th suffering from an acute strangulated femoral hernia. He complained of a chronic cough. At the operation, which was performed under open ether anæsthesia, the hernial sac was found to contain a gangrenous piece of small intestine. This was resected and an entero-anastomosis performed. The temperature rose on the first day after the operation, the maximum being on the second (103°), the day of the patient's death. He was cyanosed and breathing at the rate of 40 per minute. The pulse-rate was 130. Examination of the chest showed signs of consolidation at both lung bases. There was no displacement of the heart. The sputum was copious, rusty, and frothy.

The *necropsy* was performed eight hours after death. Both lower lobes were airless, engorged with blood, and on section exuded a creamy mixture of blood and pus. Scattered about were numerous pale areas, raised, and consisting of necrotic lung tissue. The upper lobes contained air, and exuded blood and œdema fluid on pressure. The right lung was more affected than the left. The aorta, endocardium, and other structures were stained a bright red. Sections of the lungs showed the alveoli to be filled with exudate containing large numbers of leucocytes, Gram-positive diplococci, and short-chained streptococci. In some places the alveolar wall was disappearing.

BRONCHO-PNEUMONIA.

The third is by far the largest group of the series and consisted of 75 cases. It is from the numbers of this type that the percentage incidence of post-operative chest complications is higher than in any recently published series. All cases included under this heading showed unmistakable signs of pneumonic consolidation either clinically or in the post-mortem room. Clinically the condition was recognised by impaired resonance to percussion, weak or tubular breath sounds, râles, and an alteration in the vocal resonance, which was sometimes aegophonic and at others diminished. This consolidation was, without exception, found in the lower lobes of one or both lungs. In many cases it was associated with a diffuse bronchitis.

The course of the disease was characteristic. There was a moderate rise of temperature on the first or second day after the operation accompanied by a corresponding increase in the pulse-rate. The respirations were quickened to a slightly greater degree, as would be expected in a pneumonia. The patient at this period often complained of a tight sensation in the chest and a desire to cough, which he was unwilling to gratify owing to the resulting pain in the operation wound. The onset was in some cases delayed to the third, and in one case to the fifth, day after operation. The temperature fell by lysis and in uncomplicated cases had returned to normal by the sixth to tenth day. The sputum was as a rule copious, purulent, and contained no blood visible macroscopically.

A point of interest is the rapidity of the onset in this type of post-operative complication. It would not be justifiable to claim the rise of temperature on the first day after the operation as due to the chest condition, but there can be no doubt that a fully developed pneumonia can be present on the second day, as is shown by Case 3 quoted below.

In Table I. I have placed the first and second days together owing to the difficulty of distinguishing a reactionary temperature due to the operation from that caused by the pneumonia.

TABLE I.

Day of onset.	Number of cases.
First and Second	69
Third	2
Fourth	0
Fifth	1
Doubtful	3
Total	75

This complication occurred after two main classes of operation, the first being those involving the anterior abdominal wall and by this route the peritoneal cavity, in particular the upper abdomen, the second being major operations on the mouth, pharynx, and upper respiratory passages.

Table II. gives the incidence of broncho-pneumonia in the present series :—

TABLE II.

Operation.	Cases	Pneumonias.	Deaths.	Mortality % of morbidity.
Abdominal ..	610	58 (9·5 %)	9 (1·4 %)	15·8
Mouth, pharynx, and larynx ..	52	9 (17·3 %)	9 (17·3 %)	100
Bladder and prostate (suprapubic) ..	34	3 (9·0 %)	1 (2·9 %)	33·3
Miscellaneous ..	—	5	2	40
Total ..	—	75	21	28·0

CASE 3.—Male, aged 41, admitted on August 2nd, 1927, complaining of acute pain in the abdomen. Operation showed a perforated duodenal ulcer; this was oversewn. The anæsthetic was ether, given by the open method. Nothing abnormal was detected in the heart and lungs before operation. There was no previous history of chronic chest trouble.

The temperature rose to 99·4° F. on the first day after operation. The maximum was 101° F. on the second day. It had returned to normal by the fifth day. The maximum respiration-rate was 40 per minute. Examination of the chest showed diminished movement, impaired percussion note, and weak breath sounds at the right base behind. Râles were heard at both bases, and the vocal resonance at one spot at the right side was nasal in character. The sputum was scanty and purulent. Patient died on the seventh day.

Post mortem.—The lungs showed very severe broncho-pneumonia at the lower and posterior parts of both lower lobes. The mucous membrane of the bronchi was hæmorrhagic. A small amount of sero-fibrinous fluid lay between the coils of gut and the stomach showed evidence of recent and old gastritis. The ligatures closing the ulcer were holding well. Sections of the lung showed severe, almost confluent, broncho-pneumonic consolidation, the alveoli being filled with exudate containing large numbers of polymorphonuclear leucocytes and many red blood-cells. The bronchi were filled with pus.

Case 3 is a typical example of one following abdominal surgery. There is little doubt that the peritonitis contributed to the fatal termination, but the clinical and post-mortem findings of a broncho-pneumonia at the posterior parts of the lung bases is the characteristic feature of the group in general. Microscopically, the appearance is indistinguishable from the so-called hypostatic pneumonia occurring in patients dying from such conditions as cerebral hæmorrhage and wasting diseases, and it appears to me that the clinical signs bear a close resemblance to one another.

Complications of Broncho-pneumonia.

(*a*) *Empyema.*—There was one case of empyema in the series—a man with an epithelioma of the tongue. The operation was done in two stages, the first a gland operation, the second for removal of the growth. The first operation was performed without any complications, but ten days after the second an empyema was diagnosed, opened and drained. The patient died seven weeks later from general dissemination of the growth.

(*b*) *Infarction.*—The following case is interesting in that it exhibits two types of post-operative lung complication.

CASE 4.—The patient was a woman, aged 58, operated on for carcinoma of the pyloric end of the stomach. After the operation she developed a typical post-operative broncho-pneumonia, which had almost resolved by the eighth day after operation. On the ninth she developed a femoral thrombosis, and three days later pain in the right side of the chest, blood-stained sputum, and later a well-marked friction rub.

(*c*) *Pulmonary Abscess.*—There were three such cases complicating broncho-pneumonia, but I am including one other, which I believe to be the sequela of a pulmonary infarction, making the group up to four. Three followed upper abdominal operations and one the drainage of a perinephric abscess. In the case of those complicating broncho-pneumonia, the course was typical of that condition for the first few days. Subsequently the temperature did not fall to normal as in an uncomplicated case, and examination of the chest showed signs of cavity formation confirmed radiologically in each instance.

CASE 5.—A man, aged 41, admitted on August 18th suffering from a duodenal ulcer. His lungs were emphysematous. A posterior gastro-jejunostomy was performed under open ether. The operation lasted 43 minutes. The patient had an acute dilatation of the stomach on the first day after operation. He was treated with subcutaneous saline and improved. On the fourth day after operation his temperature rose to 103·4° F., with a gradual downward trend until the thirty-second day, when it reached normal. On examination at the onset of the pneumonia the physical signs were a slight impairment of percussion note at the left base with weak breath sounds at both. The cardiac dullness was diminished, and the air entry below normal over the front of the chest owing to the emphysema. Two days later the breath sounds had decreased still more at the bases, particularly on the left side. The sputum was scanty and muco-purulent. In a further three days' time the breath sounds had become inaudible and the patient was expectorating a foul-smelling, brown-coloured sputum. From that time the signs gradually became less marked, and the patient improved. A radiogram showed a small circular shadow at the left base which in subsequent pictures became less opaque. The sputum contained pneumococci and a coliform bacillus on culture.

MASSIVE COLLAPSE.

Of the next type of complication—namely, massive collapse—there were eight cases in the series. The main physical sign on which I based my opinion was the displacement of the heart towards the side of the lesion, and without this cardinal sign of the condition I did not feel justified in making the diagnosis.

The onset was characteristic. Within three or four days of the operation the patient's temperature rose suddenly. He complained of a tight feeling in the chest and appeared to find some relief by lying on the affected side. Physical examination showed displacement of the heart towards the side of the lesion, with diminished movement, impaired percussion note, and weak or absent breath sounds. These signs remained unchanged, with the exception of the breath sounds, which frequently became of a tubular quality associated with an ægophonic vocal resonance. The temperature fell to normal again in the course of about a week, but signs of the collapse persisted for several days longer. Radiographically, displacement of the mediastinal contents was well shown with a uniform shadowing of the affected lobe of the lung. The sputum was purulent, somewhat viscid, and varied in amount. A detailed description will be found in W. Pasteur's[1] classical paper in which he points out the frequency of the condition following operations.

In the present series this complication occurred five times after an abdominal operation, twice after nephrectomy, and once after hemilaryngectomy. The last case was not diagnosed until the autopsy; death took place on the second day.

The following is given as a typical example of massive collapse.

CASE 6.—The patient was a girl, aged 15, admitted on Nov. 22nd, with signs of obstructive uræmia. She had passed little urine for several days before admission. The pulse-rate was rapid, and examination of the lungs revealed *the presence of generalised bronchitis.*

The day after admission she began to pass large quantities of urine and improved rapidly. A radiogram of the renal tract showed stones in both kidneys.

Three weeks later the stone of pure cystin was removed from the left kidney under open ether anæsthesia. Her temperature rose on the first day after the operation and remained above normal for six days, the maximum being 103° F. On the fourth day she complained of considerable pain and a sensation of tightness in the left side of her chest. Examination on the following day showed marked displacement of her heart to the left, diminished movement, dullness, and tubular breath sounds at the left lung base. These signs cleared slowly. The sputum was small in quantity, purulent, and viscid.

INFARCTION.

The last group of the series comes into a totally different category, and I have included them in the present paper in order to emphasise this difference. Although they are undoubtedly post-operative chest complications, they fall into the group of pulmonary embolisms, which in the grosser forms are so fatal. The point of difference which I particularly wish to emphasise is the period which elapses between the operation and the occurrence of the condition. In no case of the nine in the series did this complication arise before the seventh day. The onset was marked by a sharp, stabbing pain in the chest made worse by taking a deep breath, and coincident with this there was a slight rise of temperature for two or three days. The sputum, if present, was scanty and stained with bright red blood. Examination of the chest showed the presence of a friction rub, with a *slight impairment of percussion note over the same area* in the more severe cases. The following is a typical example.

TABLE III.

—	—	No. of cases.			Chest complications.						Mortality.	
					Number.			Percentage.

	Grand total ..	1478	507*	371*	115	90	25	7·8	—	—	26	1·8

* These figures are incomplete, as I considered it unnecessary to give the number of male (M.) and female (F.) cases in this category.

CASE 7.—A man, aged 55, admitted on Dec. 12th for removal of the gall-bladder for cholecystitis. The operation was performed under open ether anæsthesia. The convalescence was uneventful until the fourteenth day, when he was seized with a sharp pain in the left side of his chest. There was a slight rise of temperature for five days, and a small amount of sputum was expectorated. Examination of his chest revealed the presence of a friction rub on the left side.

PREDISPOSING CAUSES.

Table III. gives an analysis of the number of chest complications, excluding pulmonary infarctions, occurring after various operations. The percentage in this series is considerably higher than in any other recently published. But as Churchill[2] points out there has been a tendency for the numbers to rise during recent years, probably on account of a more careful study of the condition.

Site of operation.—As all other investigators have found, the type of operation which is most frequently followed by post-operative chest complications is the one involving the upper abdomen. In the present series there were 181 operations, of which 41 were followed by a lung complication (22·6 per cent.). On closer analysis of this group it was found that the highest percentage was given by the perforated peptic ulcers (40 per cent.), the next by the other operations involving the stomach and duodenum (28·7 per cent.), excluding gastrostomy. This latter operation was in every case performed under local anæsthesia, was relatively of short duration, and the amount of shock was small.

The lower abdominal operations were the other large group in which lung complications were common. Here, although the total number of complications is greater than that in the upper abdominal group, the percentage is slightly less than half (10·9 per cent.). The other types of operation following which a high percentage was noted were renal operations (11·4 per cent.), prostatectomies (8·8 per cent.), and operations on the mouth, pharynx, and upper respiratory passages (25 per cent.). It is noteworthy that in the case of radical amputation of the breast, thyroidectomy, and major head operations, the incidence was extremely low, being in the first two instances only 2 per cent., and in the last 5 per cent. These figures are significant in that they refer to operations which are as a rule lengthy and in the case of the breast involve the exposure of a large area of tissue.

From these data it appears clear that there are two classes of operation which have the greatest number of chest complications—namely, those involving the peritoneal cavity and those on the mouth, pharynx, and the upper respiratory passages. To this generalisation there is one exception, the operations on the urinary tract. These have been divided for purposes of classification into two groups, upper and lower. In the case of the former the explanation appears to be that the operation necessitates interference with structures in close proximity to the diaphragm and with the muscles employed in the act of coughing (latissimus dorsi).* In the latter instance operations such as prostatectomy are often of necessity undertaken in cases where there is severe damage to renal function. It is well known that such a condition is a predisposing factor towards the development of pulmonary infections.

Lowered resistance.—Operations in which the peritoneum was opened show that, the patients in whom it would be reasonable to expect a considerable amount of shock before operation—to wit, the "acute abdomens," are those in whom the incidence is high when compared with operations of a similar nature when conditions are most favourable. The difference is well shown by a comparison of the case incidence between perforated peptic ulcers (40 per cent.) and other gastric operations (28·7 per cent.); and again by strangulated ventral and umbilical hernias (37·5 per cent.); and similar cases where there was no strangulation (5 per cent.). There is only a negligible difference between appendicectomies whether performed for an acute or chronic condition. This is intelligible, as the shock in a patient suffering from an acute appendicitis is not marked when those cases which have progressed to a general peritonitis, an uncommon complication, are excluded.

Preoperative lung infection.—The presence of an infection of the lungs before operation appears to be of considerable importance as a possible ætiological factor. There were no notes relative to this point in 37 of the 115 cases (infarctions excluded). I was able to discover a history of either recent or long standing respiratory tract infection in 40 (35 per cent.), and in 23 of the 41 cases physical signs of such an infection were found in the lungs before operation. Amongst other investigators Elwyn[3] has noted a high percentage (25) of preoperative lung complications.

Time of year.—The monthly incidence of complications taken throughout the year in this series gives little information of value owing to great variations from month to month. If, however, the six winter months, October to March (inclusive), are compared with the corresponding summer ones, an appreciable difference is found, there being 65 in the former and 50 in the latter.

Age incidence.—An analysis of the age incidence of post-operative chest complications reveals the fact that in upper abdominal operations 39 per cent. occur in the fifth decade. The majority of this group were patients suffering from gastric or duodenal ulcers, a condition which occurs at a slightly earlier age. The lower abdominal had a more diffuse maximum, 23·4 per cent. occurring in both the fourth and sixth decades and 17·5 per cent. in the fifth. This group included a varied assortment of operations formed in large part by cases of appendicitis and inguinal and femoral hernias. I show these data in Table IV. Abdominal operations only are given as the other groups are not sufficiently large to serve any useful purpose.

From these observations it appears that one is not justified in drawing any definite conclusions as to the part which age plays in predisposing towards the condition. There is no doubt that it is uncommon before the age of 20, but it is equally true that the type of operation, following which this complication is most common, is more frequently performed in the subsequent decades. Nevertheless, I think one may say that age, in so far as it diminishes the power of an individual to withstand the ill-effects of an operation, has a *predisposing influence towards lung complications.*

TABLE IV.

Age in years.	Number of cases.	
	Upper abdomen.	Lower abdomen.
0 to 9	0	0
10 to 19	1	5
20 to 29	4	11
30 to 39	9	8
40 to 49	16	11
50 to 59	9	5
60 to 69	1	5
70 to 79	0	0
80 to 89	0	1
doubtful	1	1
	Total 41	Total 47

Length of operation does not seem to bear any intimate relation to the occurrence of the condition, as is shown by the fact that there was an incidence of 13·1 per cent. in acute appendicitis and 10·6 per cent. in the case of non-strangulated inguinal and femoral hernias, whereas radical amputation of the breast and partial thyroidectomy, both severe and relatively lengthy operations, had a percentage of only 2·1 and 1·9 respectively. This difference may be accounted for in part, but certainly not wholly, by the fact that the latter two groups were largely female.

Sex Incidence.—This brings me to the observation made by many previous observers that the condition is more common in males than females. In this series, of the 115 cases 90 were males and only 25 females. These figures are rather misleading, however, as the number of operations of a type that was followed by chest complications was greater in the former (504) than in the latter (369). The incidence, therefore, was 17·8 per cent. and 6·8 per cent. respectively.

Anæsthetic.—Table V. gives the number of anæsthetics given during the year with the corresponding number of chest complications following each. The custom at this hospital is to administer ether in some form or other unless it is contraindicated. The percentages, therefore, must not be taken at their face value, as gas-and-oxygen or local anæsthetic was given to a few cases for the very reason that a lung complication was to be feared after the operation.

TABLE V.

Anæsthetic.	Cases.	Chest complications excluding infarctions.	Per cent.
Ether	1332	93	6·9
Chloroform ..	204	14	6·8
Local and regional	179	7	3·9
Gas-and-oxygen ..	16	1	6·2
Total.. ..	1731	115	—

The number of cases in which gas-and-oxygen was employed is too small for any reliable conclusions to be drawn. In this class I have not included any minor operations such as tooth extraction, as I considered that such operations had no place in such a series. This will explain the otherwise inexplicably small number in which nitrous oxide was used.

Of the 14 cases in which chloroform was used no less than eight were operations on the mouth, pharynx, and larynx, sites which have been previously shown to be frequently followed by respiratory complications. There were four instances in abdominal operations, but the age, 82, in one of them would probably be prejudicial to an uncomplicated convalescence.

---

* This suggestion is borne out by the observations of the sisters in charge of the wards, who, owing to the nature of their work, have an unrivalled opportunity of watching the patients.

Local and regional anæsthesia was followed by broncho-pneumonia or bronchitis in seven instances. Of these, four had definite evidence of preoperative abnormality in the chest and two a suggestive history, although nothing abnormal could be found. The operations were of the lower abdominal type in all but one case.

Reference to Table V. shows that regional and local anæsthesia is followed by chest complications in 3·9 per cent. of cases as compared with 6·9 per cent. after ether, but a strict comparison cannot be made on account of the small number in the former.

MODE OF INFECTION.

There appears to be little difference of opinion between various observers as to the variety of post-operative lung complications that may occur. To put them briefly there are the pneumonias, the lobular type being by far the most common, with their attendant complications, such as abscess, empyema, and delayed resolution, which, together with bronchitis, form the majority of the cases. In a rather more doubtful group are the cases of massive collapse, and finally there are the undoubted cases of infarction of the lung.

Taking the group of bronchitis, broncho-pneumonia and its complications, it is obvious that there must be some source from which the infection arises. There are two possible theories: (1) that the infecting organisms are carried to the lung from the site of operation; (2) that the organisms are already present in the lung, or gain access to the lungs by the respiratory tract.

The supporters of the first theory must be divided into two groups. Cutler and Hunt [4] hold that the infection is carried by numerous small emboli either by the blood stream or the lymphatics from the site of operation. From the fact that the condition is most frequent following abdominal surgery they suggest that the continual movement of the anterior abdominal wall necessitated by the act of respiration serves to dislodge these emboli from the smaller vessels. This bombardment of the lungs by these infected emboli sets up an inflammatory reaction, which results in post-operative broncho-pneumonia. Razemon,[5] on the other hand, holds the view that the infecting organisms gain entrance to the lung by a lymphatic route. He points out the great number of cases which follow upper abdominal surgery, particularly operations on the stomach and duodenum, and claims to have isolated organisms from the sputum of patients suffering from post-operative pneumonia which are characteristic of that part of the alimentary tract. He suggests that the infecting organisms pass by means of the diaphragmatic lymphatics and thence through the thoracic duct to the great veins in the neck. From there they pass through the right side of the heart to the lungs, where they are filtered out. In support of the hypothesis he repeated the experiments of Bolton [6] and others on the absorption of bacteria and other minute particles by way of the lymphatics of the diaphragm.

The embolic theory put forward by Cutler and Hunt [4] would seem to meet with several objections. There is a class of post-operative lung complication which is undoubtedly due to embolism of a minor degree and which is described in papers on that subject in the same group as the cases of pulmonary embolism which result in sudden death (Lockhart-Mummery).[7] In the present series I have collected nine such cases. They have a well-known clinical course and tend to come on during the second week of convalescence from operation in the majority of cases. In this series there was not one which appeared before the seventh day.

There is no definite evidence as to the origin of the emboli. Whether they arise from the veins near the site of operation or from those of the pelvis or lower limbs has not yet been settled by the investigators of this question, but it appears to me that the picture presented by this type of case is different in many respects from that shown by post-operative broncho-pneumonia. The latter condition appears in a remarkably short time after the operation, is not characterised by the acute onset of a pulmonary infarct, and the signs and symptoms of pleurisy are rather the exception than the rule. Again, the sputum, although blood-stained in a few cases, is expectorated in moderately large quantities, and is definitely purulent in all cases.

The appearance produced by septic emboli in the lungs is nowhere better illustrated than by those cases of suppurative phlebitis of the lateral sinus following mastoiditis, or again by some cases of osteomyelitis which come to a fatal termination. Here multiple abscesses are found scattered throughout both lungs, and there would appear to be no predilection for the bases.

Armstrong and Gaskell [3] in their researches on the pneumococcal infection of the human lung state that in their opinion both lobar and broncho-pneumonia are air-borne infections, and that the factors determining the type which occur are the virulence of the infecting organism and the resistance of the host. A blood-borne infection of the lung by pneumococci they term miliary pneumonia. In this type changes in the bronchioles or bronchi are either absent or slight in comparison with those in the alveoli. These conclusions are supported by histological evidence and experimental production of pneumonia in rabbits by intratracheal insufflation of varying strains of pneumococci. From these facts it would seem unlikely that multiple embolism will explain the pathogenesis of post-operative pneumonia.

It appears to me that the grounds on which Razemon[5] bases his conclusions are also inadequate, as the bacteriological study of sputa obtained from patients who have recently undergone an operation is of little value. The organisms of the upper alimentary tract will in all probability be present from post-operative vomiting whether the patient be suffering from pneumonia or not.

The other possible mode of entry for infecting organisms is by the respiratory tract. In the first place, no one will deny that the inhalation of septic material into the respiratory passages is capable of producing an extremely severe type of pneumonia. This is well exemplified by the cases of post-operative pneumonia following operations on the mouth, pharynx, and larynx. The numbers are admittedly small, but the percentage (25) is sufficiently high to be worthy of note. Again, there is definite clinical evidence of a pre-existing chest infection in 19·6 per cent. of the 115 cases in this series and a history of either recent or chronic infection in no less than 35 per cent. Therefore it will be seen that there is a considerable number of cases in which one is justified in assuming a respiratory tract infection either before, during, or after the operation. There must be, however, other factors, and in attempting to find an explanation I was struck by the closely analogous condition of so-called hypostatic pneumonia. This type of inflammation of the lungs occurs, as is well known, in cases of wasting diseases frequently unconnected with the respiratory system.

The reason is apparent. In these cases we have patients who are for some reason or other unable to withstand a respiratory tract infection which has manifestly not arisen from any operative procedure, and there is no reason to suppose that they were infected from without by pathogenic micro-organisms. The cases are those of patients enfeebled either by old age, a chronic wasting disease, or a severe illness. In addition, such patients lie still in bed with the minimum amount of movement and take extremely shallow respirations. I would particularly emphasise instances of diaphragmatic paralysis and quote the following example at length:—

CASE 8.—A man, aged 22, who was admitted on Oct. 20th, 1926, suffering from acute anterior poliomyelitis. On admission there was complete paralysis of both legs and the right arm, which had been present for four days. Twelve hours later the paralysis had involved the diaphragm, and respirations were carried on by weakly acting intercostal and the accessory respiratory muscles. The patient was breathing rapidly and was extremely cyanosed. He died two hours later.

Post mortem, the lungs showed numerous hæmorrhages and some emphysema. There was a blood-stained froth in the trachea. The bases showed a patchy broncho-pneumonia and subpleural collapse. Heart normal. Congestion of the liver. Brain showed congestion of the blood-vessels and a few subarachnoid hæmorrhages.

Sections of the lungs showed a hæmorrhagic broncho-pneumonia.

The changes in the brain and cord were typical of anterior poliomyelitis and polio-encephalitis.

Here it will be seen that a broncho-pneumonia was present in addition to the small areas of collapse. Pasteur [1] has emphasised the occurrence of the latter condition in similar cases, especially in post-diphtheritic diaphragmatic paralysis.

It would appear that the procedure involved in operations, particularly those on the upper abdomen, tends to reproduce the conditions necessary for the production of such a pneumonia. The patient has been subjected to treatment which tends to lower his resistance to any infecting organisms present in his respiratory tract, and on recovering from the anæsthetic is conscious of a pain in his abdomen which is made worse by any attempt at coughing or taking a deep inspiration.

The respiratory movements which are most involved are those of the diaphragm, which, as was shown by Keith,[9] are responsible for the ventilation of the bases and posterior parts of the lungs, and it is this movement which is especially painful to patients who have undergone an upper abdominal operation. It is interesting to note the relatively high percentage (11·4) of post-operative complications following renal operations, which involve the structures in the region of the pillars of the diaphragm and the latissimus dorsi muscles. Drummond,[10] in 1898, notes that patients who made the most successful attempts at coughing made the best progress.

In support of the contention that inhibition of the diaphragmatic movements occurs may be cited Churchill and McNeil's[11] observations on the vital capacities of patients before and after operation. They found that the vital capacity on the first day after operation was of the following order:—

Gall-bladder operations	25	Per cent. of the preoperative capacity.
Chronic appendicitis ..	60	
Inguinal hernia (Bassini)	50	
Non-abdominal	100	

These observations appear to be of the first importance and demonstrate the marked effect that an abdominal operation has on the ventilation of the lungs especially in the case of the upper abdominal group. In addition to this Christie and Beams's[12] experiments on the vital capacity of subjects lying down and sitting are illuminating. They found that in a series of 290 normal men and women there was a decrease of 5·5 per cent. in the prone as compared with the sitting posture. This, as would be expected, was accentuated in obese women.

There are therefore three main conditions necessary for the production of a post-operative pneumonia: (1) The presence of organisms in the lungs, either before the operation or aspirated during the period of unconsciousness at operation or soon afterwards. (2) The inhibition of the respiratory movements and in particular those of the diaphragm consequent on the surgical procedure. (3) The lowering of the patient's resistance.

Turning to the actual pathological process by which the pneumonia is produced apart from the route of infection, which has already been discussed, Elwyn [3] has suggested that the pneumonic consolidation is preceded by areas of collapse in which the infecting organisms find a "locus minoris resistantiæ." Churchill [2] has, however, pointed out the fact that pneumonia is an extremely rare complication of collapse of the lungs when produced artificially, such as with a pneumothorax for pulmonary tuberculosis or bronchiectasis, conditions in which there is a severe infection of the pulmonary tissue. From my own personal experience of this method of treatment I can substantiate this statement.

Mastics, Spittler, and McNamee,[13] and more recently Boland and Sheret,[14] have gone a step further and claim that a very large proportion of all post-operative lung complications are in reality varying degrees of collapse of the lungs. In answer to this conception I would point out the fact that it is a common occurrence to find lungs from patients dying shortly after operation with broncho-pneumonia in which there is no evidence of collapse, and although the occurrence of pneumonia together with areas of collapse is by no means a rarity, it would seem improbable that the collapse predisposes to the pneumonia.

A more likely explanation appears to be that the pneumonia is preceded by an infection of the bronchioles as has been demonstrated by Armstrong and Gaskell [8] in the case of a broncho-pneumonia of a pneumococcal origin, and should the exudation into the bronchi be of sufficient viscosity and allowed to remain owing to the inhibition of the cough reflex, a collapse will result. This conception agrees with that of Elliott and Dingley,[15] who showed that the blocking of the bronchi by inflammatory secretions was the most probable explanation of the phenomenon of massive collapse. That these secretions are capable of producing a collapse has been shown by Lee, Tucker, and Clerf,[16] who brought about the condition in dogs by introducing the bronchial secretion of a patient with the disease or a solution of gum acacia of a similar viscosity, the cough reflex having first been inhibited by drugs.

TREATMENT.

The treatment naturally divides itself into two phases: (1) prophylactic and (2) curative. The first may be divided into treatment before, during, and after operation. In my opinion greater attention should be paid to the examination of the chest for evidence of inflammation of the respiratory tract and a closer inquiry into the history of recent coughs and colds. At operation every effort should be made to protect the patient from exposure to circumstances which tend to lower his resistance, and during the first two or three days after operation the patient should be encouraged to move himself as much as circumstances will permit, and to practise taking deep inspirations. With the latter point in view, during the year 1928, patients in two wards, one male and one female, were instructed to blow water from one Woulfe's bottle into another connected to it by rubber tubing, the underlying idea being that the effort would induce deeper inspirations and thus reduce the area of inactive lung. The results were compared with those from two similar wards in which respiratory exercises were not given. They are as given in Table VI.

TABLE VI.

Type of operation.	Wards in which exercises were employed.			Wards in which no exercises were employed.		
	Cases.	Complications.	Per cent.	Cases.	Complications.	Per cent.
Upper abdomen	82	19	23·3	48	8	16·6
Lower abdomen	153	16	10·6	154	12	7·7

I have only included abdominal operations owing to the fact that the other types were in too small numbers. The results of this treatment are disappointing as any difference that is shown is in favour of the untreated class. The real reason for the failure is that the method takes no account of the human element. The average patient will not take inspirations, if such respirations are going to cause him considerable pain.

A further attempt to aerate the lungs was made by giving the patients a mixture of 50 per cent. CO_2 in air delivered through a nitrous oxide gas apparatus 24 hours after the operation. It was found that the patients would not tolerate the administration; it was too reminiscent of the operation they had just undergone. Scott and Cutler[17] published a preliminary report advocating the use of CO_2 as a prophylactic measure against massive collapse. The percentage of the gas was varied at the discretion of the administrator. It was given immediately after the operation, during the unconscious period, and would overcome my difficulty.

More recently Scott,[18] Coryllos,[19] and Yandell Henderson[20] have published papers emphasising the usefulness of CO_2 in the treatment of massive collapse and post-operative pneumonia. At this hospital the method is being given a trial, but so far no statistical evidence is obtainable.

The curative treatment of post-operative lung infections again resolves itself into an attempt to re-expand the lung bases, and similar methods to those outlined above may be tried. In addition, an expectorant mixture to assist in the coughing up of sputum is useful. Other treatment is purely symptomatic.

CONCLUSIONS.

(1) Post-operative chest complications may be divided into two groups: *(a)* Those due to an infection of the lungs and resulting in bronchitis, broncho-pneumonia, and their complications. *(b)* Those due to pulmonary embolism and resulting in either infarction of the lung or sudden death of the patient.

(2) Post-operative bronchitis and broncho-pneumonia are the result of an infection which reaches the lungs by way of the respiratory tract and which is either present before the operation or gains entrance thereto during or soon after the operation. General anæsthetics are in this way indirectly responsible for post-operative chest infections, because infected material may be aspirated during their administration.

(3) The other important factors are the lowering of the patient's resistance and the stagnation in the lower lobes of the lungs caused by the position of the patient and the immobility of the diaphragm and during the first two or three days after operation.

(4) Massive collapse of the lung is probably of a similar ætiology to post-operative pneumonia, but there is no reason to believe that it is an essential predisposing cause to the pneumonia.

I should like to thank the Surgical Staff of University College Hospital for allowing me to examine the cases that came under their care during the preparation of this paper.

THE ACTION OF
ALCOHOL UPON THE BLOOD-SUGAR IN DIABETES MELLITUS.

BY T. C. HUNT, B.M. OXF., M.R.C.P. LOND.,
MEDICAL REGISTRAR, ST. MARY'S HOSPITAL.

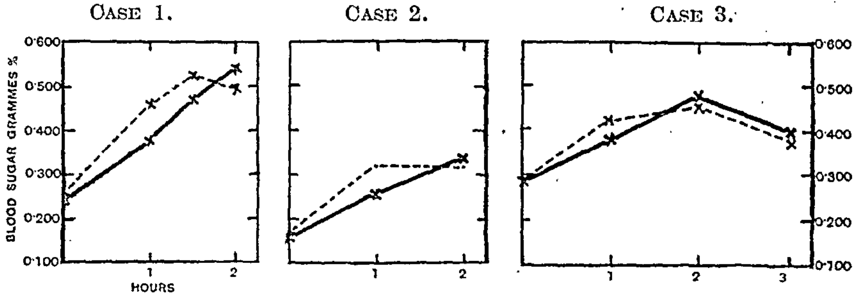
THERE is considerable difference of opinion about the value of alcohol in the treatment of diabetes mellitus, but that it has a use in this condition can hardly be doubted. Since alcohol can spare fat, approximately in the ratio of the calorie values of the two substances—i.e., 7 to 9—it must clearly be considered a valuable foodstuff, and since there is no evidence that it can itself form carbohydrate in the body, it appears at first sight to be a particularly suitable source of energy in diabetes. Few clinicians, however, are prepared to lay great stress upon the actual food value of alcohol, because, viewed in terms of calories alone, it can almost always be readily replaced by other substances. On the other hand, there are important considerations apart from its simple energy value. It has a place as a mental sedative in periods of partial or complete starvation, and as an aid to appetite, and it makes the often one-sided diets of the diabetic more palatable.

More important still is its action upon the hyperglycæmia, glycosuria, and ketonuria of diabetes, and a large amount of work has been done on the effect of alcohol upon the amounts of sugar and ketone bodies passed in the urine. On the whole, this work has shown some diminution, both in the glycosuria and in the ketonuria, but only when moderate amounts of alcohol have been given; excessive quantities have consistently produced the reverse effect. This has especially been noted when the excessive alcohol intake has been sufficient to raise the total calorie intake above a maximum optimum level.

Allen and Wishart in two cases saw increased sugar output when moderate amounts of alcohol were added to the diet, and Joslin and Allen in America have almost abandoned its use. On the other hand, almost all workers are agreed that alcohol possesses a definite antiketogenic value (Allen and Wishart, Higgins and collaborators, Neubauer), and most continental authorities advocate its use to lessen both glycosuria and acidosis. Thus van Noorden never observed an increase, but often a fall, in glycosuria on the addition of alcohol to the diet in diabetes, and Kalz, in a study of 12 diabetics, found no disadvantage from the daily consumption of a [illegible] of strong, but as far as possible sugar-free, [illegible] Neubauer, Hirschfeld, Benedikt, and Torok [illegible] others (quoted by van Noorden) who have [illegible] shown a beneficial action upon the condition [illegible] urine after the consumption of alcohol.

Results have been less consistent when the [illegible] the blood-sugar has been examined, and [illegible] undoubtedly been partly due to variations [illegible] Allen and Wishart observed a temporary [illegible] the blood-sugar after giving alcohol [illegible] This effect in some cases was cons[illegible] prolonged luxus rations of mixed fat [illegible] to marked hyperglycæmia; Hetenyi [illegible] responses in the hyperglycæmia [illegible] grammes of alcohol (approximately [illegible] Leclercq, by giving an excessive [illegible] the diet, together with alcohol [illegible] raised the blood-sugar in two [illegible] diabetes to very high values—[illegible] to 0·319 per cent. Fuller, [illegible] noted a reduction in the hyper[illegible] in amounts from 5 to 30 c.cm. [illegible] for part of the fat in the di[illegible] simple addition to it.

Large amounts of alcohol [illegible] toxic action upon the [illegible] Albertoni's experiments [illegible] heavy administration of [illegible]



the alimentary hyperglycæmia after 100 g. of glucose much more marked than in the normal animal after a similar dose of sugar. If this action is avoided, the effect, if any, appears to be rather to reduce than to raise the blood-sugar, a change which Gavrila and Sparchey found more marked in the diabetic than in the normal; giving 0·4 g. of absolute alcohol (well diluted) per kilogramme of body-weight, and using plain water as a control, they recorded a fall in blood-sugar, half an hour after the alcohol ingestion, as great as 75 per cent. of the fasting value in some of the six diabetics whom they examined. Such an insulin-like action, if confirmed, is clearly of considerable importance, and, if constant, must obviously be taken into account in the consideration of some of the experimental results obtained by the use of insulin substitutes given by the mouth in alcoholic solution. Thus Blatherwick and collaborators found that insulin given in dilute alcohol per os caused a 30 per cent. reduction of the blood-sugar, and many plant extracts advocated in diabetes as possessing insulin-like activity are, in fact, given in strong alcoholic solution. It is significant that the blood-sugar sinking substances extractable from almost all vegetable cells have mainly been prepared from alcoholic solution, as have many of the similar substances obtained from animal tissues.

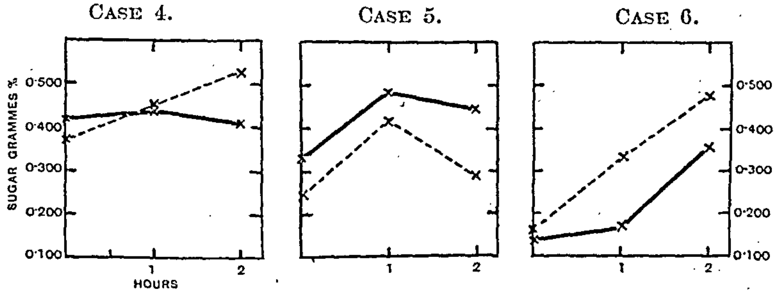
Experimental Results.

It seemed therefore worth while to study this question again in a number of diabetic patients, especially from the point of view of the action of alcohol, in a form most commonly ordered, upon the fasting blood-sugar. No detailed examination was made into the action upon glycosuria or ketonuria, since our knowledge on these points is full, and for the most part unanimous. The patients examined were all at rest in bed in the Medical Unit Wards of St. Mary's Hospital, and I am greatly indebted to Prof. F. S. Langmead, director of the unit, for permission to carry out these investigations. The procedure employed was as follows:—

The fasting blood-sugar was examined at 10 A.M.—no previous food or drink having been taken since 8 P.M. the night before—and again at 11 A.M., after which a dose of brandy, either a half or one ounce according to age, was immediately given in 4 ounces of water. The blood-sugar was then re-examined one hour and two hours later—i.e., at 12 noon and 1 P.M. Two estimations of the fasting level were made in order to detect any unsuspected tendency of the blood-sugar to fall, an inconstancy which, however, after a sufficiently long fast, is, in my experience, unusual.

Seyderhelm and Oestreich find that the blood-sugar in diabetes shows the highest value in the morning, and tends, in the majority of cases, to fall gradually during the day, but Nielson, studying the fasting level at frequent intervals, did not observe the variations or "pulsation waves" described by others. I have failed to observe changes, outside the limit of error of the method employed, on repeated examination during the same day. It may, I think, be accepted that there is no inherent tendency of the true fasting level to fall, at least in the course of a few hours. The estimations of the blood-sugar were carried out by Calvert's modified MacLean's method, the limit of error being in my hands not greater than 10 mg., except in cases showing exceptionally high values. In most cases duplicate estimations were performed, the mean value being taken when these two differed.

The results are recorded in Table I. It will be seen that in every case a fall took place, the lowest being of 32 mg., the highest of 122 mg.; this fall occurred mainly at the end of one hour, though in a few cases it was most marked at two hours. The average extent of the drop in the ten cases was 58 mg. The brandy used contained approximately 40 per cent. of alcohol by volume, so that the amount of alcohol given in one ounce was approximately 14 c.cm., with a caloric value of 98, or roughly the equivalent of 25 g. of carbohydrate.



Charts showing blood-sugar curves, in six cases, following ingestion of 50 g. glucose (continuous lines) and 50 g. glucose plus 1 oz. brandy (interrupted lines).

In order to determine if possible whether this fall in blood-sugar was brought about by a direct action of the alcohol upon the gastric or duodenal mucous membrane or was the result of its action after absorption into the blood stream, a similar dose of brandy was given with similar precautions by the rectal route. In two control cases of diabetes a rectal wash-out, followed by the injection of 4 oz. of water, caused no appreciable change in the level of the fasting blood-sugar. The results in three patients given 1 oz. of brandy in 4 oz. of water are shown in Table II. It will be seen that the fall produced is very similar to that observed when the drug was given by mouth.

TABLE I.—*The Effect of Brandy by Mouth upon the Blood-sugar in Diabetes Mellitus.*

No.	Sex and age.	Fasting level. (1)	Fasting level. (2) (1 hour later.)	Dose of brandy in ounces.	Blood-sugar— First hour.	Blood-sugar— Second hour.	Blood-sugar— Fall (max.) mg.
1	F., 65	0·181	0·181	1	0·142	0·127	— 54
2	F., 64	0·340	0·340	1	0·330	0·252	— 88
3	F., 9	0·255	0·248	½	0·218	0·216	— 32
4	F., 51	0·155	0·153	1	0·104	0·097	— 56
5	M., 8	0·397	0·395	½	0·324	0·377	— 71
6	F., 46	0·130	0·127	1	0·097	0·088	— 39
7	M., 9	0·390	0·396	½	0·274	0·306	—122
8	F., 28	0·217	0·220	1	0·184	0·223	— 36
9	M., 54	0·140	0·140	1	0·089	0·100	— 51
10	F., 46	0·410	0·409	1	0·375	0·379	— 34

Blood-sugar in grammes per 100 c.cm. blood.
Average fall 58 mg.

It may thus be inferred—though three cases only were examined—that alcohol is not only absorbed from the rectum (as is well known) but that it exercises comparable effects upon the blood-sugar by this route to those following its ingestion by mouth.

Alcohol Plus Food.

Six patients were examined with the object of determining whether this hypoglycæmic action of brandy in diabetics could also be observed when it was given together with carbohydrate in the form of the customary sugar tolerance test; it was hoped in this way to obtain insight into its effect when given with food. For this purpose 50·0 g. of glucose and 1 oz. of brandy in 4 oz. of water were given, and blood-sugar estimations were made at intervals of one and two hours. The test was repeated after an interval of not less than two days, using the same dose of glucose but omitting the brandy. For many reasons such procedures are open to certain errors, and few definite conclusions can be drawn from the curves obtained. Thus it is important to allow an interval of time between the two tests, since administration of 50·0 g. of sugar to a diabetic may seriously affect his carbohydrate tolerance for at least 24 to 48 hours; moreover, intervening diet may undoubtedly influence the shape of the curve.

TABLE II.—*Alcohol Administered Per Rectum.*

6	A	0·136	0·166	—	0·356	—
	B	0·154	0·330	—	0·475	—

A = 50 grammes glucose, ℥iv. water. B = 50 grammes glucose, ℥iv. water, and ℥i. brandy. Blood-sugar in grammes per 100 c.cm. blood.

There is often an appreciable change in the sugar curve when it is examined on successive occasions, and it is known to vary rapidly with alterations in the carbohydrate content of the previous diet. In these cases the alcohol-sugar-test was first carried out, and after an interval of two to five days (in four cases three days, one case five days, and one case two days) the simple sugar test was performed. The curves of the six cases are here illustrated, and the blood-sugar values are shown in Table III. As will be seen no great variations are observed, and the only constant feature noticeable is that in all the patients a more rapid rise of blood-sugar occurred when the alcohol was given with the glucose than when the latter was given alone. Thus in all cases the increase in blood-sugar at the end of one hour was greater in the former than in the latter, the mean value of this excess rise (above that shown with the glucose alone) in the six cases being 65 mg. The maximal level reached was slightly higher with glucose alone than with glucose plus brandy in four cases; in one case the latter was considerably higher, and in one appreciably so. Although the curves obtained are by no means strictly comparable, yet the alcohol curve shows a sharper and more rapid rise, while the actual height reached is but little affected; in five of the six cases the rise during the second hour was greater with the glucose alone than with the glucose and brandy together.

It may thus be concluded that the effect produced by alcohol is that of causing a more rapid absorption of sugar into the blood, and a quicker rise in the level of the blood-sugar; time is affected more than actual level. Such a result is to be expected when it is remembered how alcohol is able to aid the absorption of substances from the stomach. Edkins, giving glucose through a stomach tube to cats anæsthetised with ether, found that the rate of disappearance of the glucose from the stomach was twice as great when it was given with alcohol as when given alone. It is thus clear how such increased rapidity of absorption may lead to the changes noted in the form of the blood-sugar curve in the cases here recorded.

Conclusions and Discussion.

A "medicinal" dose of brandy is capable of lowering the fasting blood-sugar in a diabetic, and this action is brought about after absorption of the drug into the blood stream. The exact mechanism is not easily explained. It is possible that it is brought about through an action of alcohol upon the liver, by which the function of this organ in "secreting" glycogen is improved, since alcohol may be more readily burnt and more storage of sugar can take place; in other words, a true carbohydrate-sparing effect may be produced. Some work upon the alteration of the respiratory quotient after the ingestion of alcohol supports the suggestion, and this action might well account for part of the obesity frequently seen after prolonged consumption of alcoholic liquors. It is doubtful, however, to what extent, if any, alcohol can replace carbohydrate in the body. Galami, by a simultaneous study of the blood-sugar and alcohol curves in the blood after ingestion of sucrose and alcohol, found that the two curves ran independently, and that alcohol was not used directly in muscular contraction—i.e., no replacement of carbohydrate by the alcohol took place. Another possible mode of action is that alcohol might directly excite the islet tissue, perhaps through a reflex increase of blood-supply resulting from vasodilatation of the vessels supplying these cells. Alcohol has a powerful stimulant effect on gastric secretion not solely due to its local action upon the mucous membrane. Steinitz and Schereschewsky found that 300 c.cm. of 5 per cent. alcohol given per rectum caused a rapid and copious secretion of gastric juice, the maximum flow occurring in 15 to 30 minutes; glucose, water, saline, and other solutions similarly administered had no such effect. There is, moreover, some evidence (Gley and Hazard) suggesting that the entrance of hydrochloric acid into the duodenum may provoke some secretion of insulin into the blood; it undoubtedly increases the output of external pancreatic secretion.

Thus alcohol, through its stimulant action upon gastric secretion and an increased production of "secretin" and of pancreatic secretion, might in this way provoke a moderate output of insulin itself. Zunz and La Barre, Novoa Santos, and others have shown a relationship between duodenal secretion and insulin production, and Onodera records marked lowering of the blood-sugar by the action of salts upon the duodenal mucosa. Whatever the precise explanation it is certain that alcohol has no specific individual action upon islet tissue, nor is the action in lowering blood-sugar in diabetes confined to alcohol alone, since many other substances possess a similar property. At the same time brandy is a readily available drug, and its associated actions may at times make it a particularly valuable one in therapeutics. In diabetic coma it would seem to be of value, either by mouth or per rectum; moderate amounts as an addition to, or substitute for, part of the diabetic diet appear to have no detrimental influence upon the hyperglycæmia. Given with sugar it increases the rate of absorption from the stomach, but does not necessarily cause a higher concentration of glucose in the blood than is produced when sugar is given alone. Its value in non-diabetic conditions, when increase in nutrition is desired, has some support from this conclusion.

My thanks are due to Prof. Langmead, Director of the Medical Unit of St. Mary's Hospital, for his kindness in giving me facilities for carrying out these tests.

SPINAL ANÆSTHESIA.

A CRITICISM OF THE PITKIN METHOD.

BY E. FALKNER HILL, M.B. VICT., D.P.H.,

LECTURER IN ANÆSTHETICS IN THE UNIVERSITY OF MANCHESTER.

AT the Manchester meeting of the British Medical Association last year, Dr. F. A. Kelly, of Detroit, U.S.A., speaking of the method of anæsthesia recommended by Dr. George Pitkin, of New Jersey, said that "Dr. Pitkin . . . has worked out a technique which to my mind does away with the objections to the older methods of spinal anæsthesia. The main objections in the past have been, first, the transitory nature of the anæsthesia; secondly, lack of control of the height or extent of the anæsthesia; thirdly, the serious depression of the blood pressure. The technique devised and advocated by Dr. Pitkin . . . completely negatives all of the above objections and with them other objections that one so often hears."[1]

Dr. Kelly, who demonstrated the Pitkin method in August, 1928, injected a fluid lighter than the cerebro-spinal fluid and containing 100 mg. of novocain per c.cm.; 1·1 mg. of strychnine and 14½ per cent. alcohol made up to 2 c.cm. with normal saline. The fluid also contained a body derived from starch and called "gliadin" or "amyloprolamin." He mixed this fluid with more or less cerebro-spinal fluid as required, and having injected it he tilted the table to direct the injection to the particular region he wished to influence. None of these procedures is new. It is possible that "gliadin" is new in this connexion, and though novocain and alcohol have both been used before as constituents of an intrathecal injection they may not have been used in combination. It is certainly a most valuable combination, and if Dr. Pitkin is responsible for this he has made a notable contribution to the practice of spinal anæsthesia. The function of gliadin seems to be to hold the injected solution together "as an air bubble on a spirit level" and to delay the absorption of the novocain so that toxicity is reduced and anæsthesia prolonged. By this means Dr. Pitkin is able to give much larger doses than have hitherto been given—up to 400 mg. or even more if necessary.

FIG. 1.

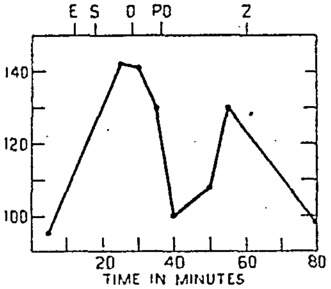

Chart showing blood pressure during operation. E = Ephedrine, 5 per cent.; novocain, 1 per cent. 1 c.cm. S = Spinocain, 2 c.cm. O = Operation begun. P.O. = Peritoneum opened. Z = Operation finished. The blood pressure before operation was 94 mm. and it remained above this level during the operation which was a complete abdominal exploration. After 45 mins. (i.e., 5 mins. after the operation was finished) *the anæsthesia as tested by* towel forceps was above the clavicles.

Dr. Pitkin states that "if the anæsthetic fluid is confined to the lumbar spine there is no change in the blood pressure; if it reaches the first thoracic the pressure becomes nil."[1] The record of blood pressure given in Fig. 1 shows that, at any rate in this dogmatic form, this statement cannot be accepted. The blood pressure usually falls below the normal in a complete laparotomy with the anæsthesia extending above the clavicle, but in this case it did not. Dr. Pitkin regards a large fall of blood pressure as one of the objections to the older methods of spinal anæsthesia. Figs. 2 and 3 show blood pressure records taken from patients anæsthetised by the Pitkin method; they were both desperate surgical risks and both made excellent recoveries, in part due to the protection afforded by the spinal anæsthesia. The technique, however, did not prevent a fall in blood pressure.

Are we to conclude that a fall of pressure does not matter or that some falls do matter and others do not? If, at the end of a long surgical operation with much visceral manipulation, shock or hæmorrhage, the blood pressure falls steadily, progressively and extensively, then indeed the fall is the index and measure of the gravity of the situation. If, on the other hand, a fall is produced by injecting half a dozen grains or so of novocain into the spinal theca and paralysing a vaso-constrictor or two, the fall should be regarded as an indication of the amount of vaso-dilatation, and the need for some degree of the Trendelenburg position, but not as a sign that the situation has developed into one of unexpected gravity. The fear of a fall of blood pressure is a relic of a different technique in which the anæsthetic solution was heavier than the cerebro-spinal fluid and was not fixed. The patient had to sit up, the Trendelenburg position was not available, and a dangerous anæmia of the medullary centres might appear.

The Pitkin method is valuable, therefore, not because it completely negatives a large fall of blood pressure, but because in the circumstances of a modern operation a large fall of blood pressure is not greatly to be feared. The passing danger of anæmia of the medulla is overcome by the Trendelenburg position and the heart, accustomed to work against a pressure of 200 mm. of mercury, finds itself relieved of three-quarters of its burden, presumably to its advantage.

In these cases of high blood pressure the pressure is doubtless a response to some subtle need of the organism, but the subsequent histories of my cases do not suggest that the need is so imperious that it can suffer no remission, while the surgeon removes its cause, or a large factor of its cause. When the anæsthesia reaches as high as or higher than the second dorsal, why is it that we find sometimes a big fall in blood pressure, at other times little or none? It may be possible to anæsthetise the posterior roots and not the anterior, and as the vaso-constrictor fibres pass out by the anterior roots through the white rami communicantes to join the splanchnics, they may possibly escape the action of the novocain. The last word has not been said on this question and the time for dogmatic statement is not yet.

---

Strychnine.

Dr. Pitkin says: "We conducted a series of tests and animal experiments with all the drugs that have been advocated as vaso-constrictors. Strychnine, intradurally, was the only one that showed satisfactory results in the presence of novocain."[1] So far as I know, he has published no experiments in support of this statement. With reference to the effects of therapeutic doses of strychnine on the blood pressure Sollmann says: "These effects are so inconstant and small that they could be accidental."[2] When strychnine has been applied to the cord direct there is no mention of a rise of blood pressure. The case for the rise of blood pressure is not proven. The great characteristic action of strychnine is to break down the internal resistance of the spinal cord so that a definite stimulus produces a bigger motor response than in normal conditions. This leads to the early onset of rigidity and puts the patient into a state diametrically opposite to the one desired by the anæsthetist, who wants a smaller response to a given stimulus. He wants the passage from one side of the reflex arc to the other made more difficult, and the internal resistance of the spinal cord increased. On theoretical grounds, then, strychnine would seem to be contra-indicated. Clinically, it is interesting to note that Jonnesco,[3] who has had a longer experience of spinal anæsthesia than anyone in Europe, has given up intrathecal strychnine after 15 years' trial. Both adrenalin and ephedrine will raise the blood pressure, even after destruction of the splanchnic nerves, so that there seems no object in using a drug like strychnine for this purpose. The reasons against it are overwhelming; they are: (1) there is little reason for supposing that we require to raise the blood pressure; (2) there is no convincing evidence that strychnine will raise it; (3) other drugs will; and (4) strychnine produces a state exactly opposite to the one desired.

FIG. 2.

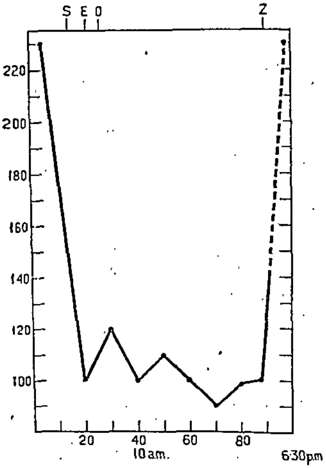

Chart of blood pressure during operation on a woman, aged 63, with a fistula between gall-bladder and duodenum. The gall-bladder was excised and the duodenum stitched up, the operation lasting 50 minutes. S = 2 c.cm. spinocain. E = 1 c.cm. ephedrine, 5 per cent.; novocain, 1 per cent.. O = Operation begun. Z = Operation finished. During operation the blood pressure fell from 230 to 90 mm. Hg. A few hours later it had fully recovered.

FIG. 3.

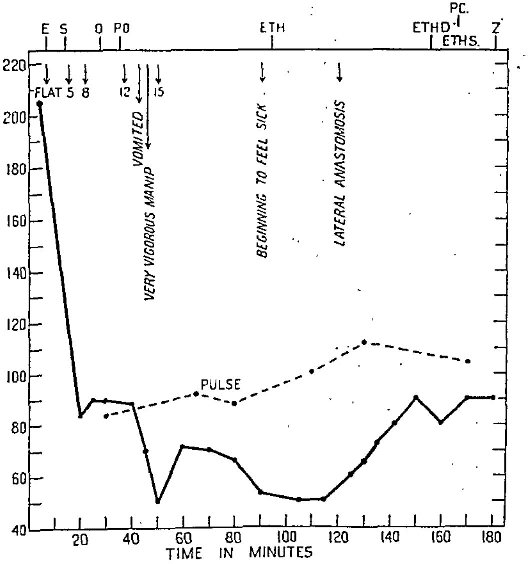

Chart showing blood pressure of a male, aged 65, during resection of growth of colon. E = Ephedrine, 5 per cent.; novocain, 1 per cent. 1 c.cm. S = Spinocain, 2 c.cm. O = Operation begun. P.O. = Peritoneum opened. ETH. = Ether. ETH.D. = Ether deepened for stitching peritoneum. P.C. = Peritoneum closed. ETH.S. = Ether stopped. Z = Operation finished. Flat 5, 8, 12, and 15 = degree of slant of table, head down. The chart shows a fall of blood pressure from 205 mm. Hg to 50 mm. Hg. It also shows a slow steady rise, presumably due to the gradual absorption of the spinocain. The pulse-rate was 104 at end of operation lasting 2 hours 32 mins. Patient made a good recovery.

Messrs. May and Baker have kindly made for me a solution resembling spinocain but containing no strychnine, and it has given clinical results in no way inferior to those of spinocain. Whereas the two biggest falls of blood pressure (Figs. 2 and 3) I have seen occurred in patients who were anæsthetised with spinocain, the longest anæsthesia I have seen, in which there was complete muscular relaxation and absence of pain for one and three-quarter hours, was done under this strychnine-free preparation.

Controllability.

Under this heading come the three factors of height, duration, and intensity. Almost anything may result from extracting 2 c.cm. of cerebro-spinal fluid from the theca between the third and fourth lumbar vertebræ and reinjecting it mixed with 2 c.cm. of spinocain; there may be anæsthesia extending downwards from an inch below the nipple line, or only from an inch below the umbilicus, the patient being in the Trendelenburg position 5°. If expansion is essential for a high anæsthesia, how is it that a high and long anæsthesia is produced when only 2 c.cm. of cerebro-spinal fluid have been extracted? It is not very rare to be able to do a laparotomy under these conditions.

---

[3] Jonnesco, T: Presse. Méd., 1926, xxxiv., 145.

Duration again is a variable quantity. One hour is generally available for laparotomies after the administration of 2 c.cm. of spinocain. The longest time I have ever seen was one and three-quarter hours, but this was after the injection of 3 c.cm. of the strychnine-free preparation made for me by Messrs. May and Baker; pain and rigidity were completely in abeyance for the whole of this time. When the anæsthesia passes off it does so by the oncoming of pain or rigidity. As the case whose blood pressure record is shown in Fig. 5 illustrates a number of these points, I shall describe it in detail.

The patient was a strong, muscular young man of 28. He had had more than one hæmorrhage from the bowel, and a provisional diagnosis of duodenal ulcer had been made. In view of a probable gastro-enterostomy, a high anæsthesia was required, and 3 c.cm. of spinocain were mixed with 5 c.cm. of cerebro-spinal fluid and injected into the theca between the first and second lumbar vertebræ. The anæsthesia and the muscular relaxation were good On opening the abdomen a diseased Meckel's diverticulum was found; this was removed, as was also the appendix. The surgeon then turned to me and said "You must give him some ether." I said "What for? He's not feeling anything." This was confirmed by the patient. However, the abdominal walls were too rigid to proceed without ether. This conversation took place one hour and two minutes after the injection of spinocain. The assistant surgeon, who had come 40 minutes late, said that he had noticed that the muscles had been getting more and more rigid ever since his arrival—that is to say, 20 minutes before the surgeon asked for ether, up to which time the patient had felt no pain. The path of pain to the brain was blocked, but the spinal reflex was not. No root anæsthesia could account for this. The spinal cord was blocked high up, but free lower down.

This means that the novocain is high in the dorsal region, where it is not only anæsthetising the roots of the nerves but the cord as well, and so preventing pain. The spinothalamic tract, the path of pain, is blocked. The original muscular relaxation (abdominal) must have been due to a portion of the spinocain left behind by the main mass during its ascent to the higher dorsal region, but these trailing clouds have been absorbed leaving the lower cord free and—thanks to the strychnine—in a highly excited condition, thus accounting for the rigidity.

The evidence from this case, then, tends to show: (1) That the anæsthetic affects the cord (spinothalamic tract), as well as the posterior roots. (2) That the spinocain does not remain en masse. (3) That strychnine is contra-indicated. (4) That the commonly accepted idea that the anæsthesia passes off from above downwards is that particularly dangerous form of fallacy, a half-truth; it does pass off from above downwards, but equally from below upwards. (5) That in those cases in which it is only possible to extract 1 or 2 c.cm. of cerebro-spinal fluid, the anæsthesia required for a laparotomy can be attained if the resulting 3 or 4 c.cm. of mixture can be placed in contact with the cord in the region of the sixth, seventh, eighth, ninth, and tenth posterior dorsal roots. I have records of such cases.

C. A. Pannett[4] has shown that the dural sac is inextensible, and tends to assume the form of a cylinder. A semi-mucilaginous fluid injection which remains en masse should assume the form of a cylinder too, its length depending upon its bulk. Assuming that this anæsthetic solution is absorbed at the same rate all along the line—a reasonable assumption—the anæsthesia should pass off all along the line, at the moment when the concentration of novocain in the solution becomes a sub-anæsthetic concentration. It is doubtful if this ever happens in practice, but there is definite evidence that anæsthesia no longer exists at an area where, a few minutes before, it had existed, coupled with the existence of anæsthesia, both then and now, in a neighbouring segment. A case will illustrate my meaning.

A fistula in ano came to operation on July 12th last. Two cubic centimetres of spinocain were mixed with one cubic centimetre of cerebro-spinal fluid and injected, the patient being in a 5° Trendelenburg position. The operation lasted 25 minutes and was painless. The last step of the operation was the insertion of two stitches, which was painful. The patient winced at each prick of the needle, and remarked that the numbness was passing off. I pinched the skin over both calves immediately after, and again 5, 10, and 15 minutes later, and he could feel nothing, and said: "It's no use, I can't feel anything below the knees." Here, then, the fifth sacral and coccygeal nerves had been anæsthetised, but the anæsthesia had passed off while the fifth lumbar and first and second sacral segments were still anæsthetised. The anæsthetic area had contracted, but had not been extinguished all along the line at the same time.

FIG. 4.

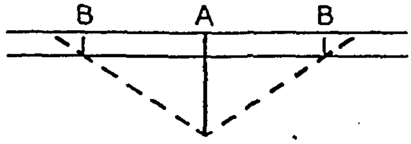

Diagram to illustrate the absorption of spinocain from the theca. The areas supplied by region (A) of the cord and its roots will be under the influence of spinocain longer than the areas supplied by regions at (B).

The shape of the injected solution, supposing the bulk of it to remain en masse, must be roughly triangular or semi-hemispherical (Fig. 4). The deepest part of the solution will be at the point of injection (or where the solution settles itself), becoming less deep on either side; the depth of anæsthesia will correspond to the depth of the solution.

Criticism of Dr. Kelly's Statement.

With a high dorsal anæsthesia the change in blood pressure may vary from a fall of 154 mm. of mercury to an actual rise above the preoperative reading; with the same dose, the same mixture, and the same slant of the table there may be a variation of four spinal segments—sixth to tenth dorsal—in space, and nearly 100 per cent. (35–85 minutes) in time. This is controllability, perhaps, but limited controllability.

Dr. Kelly mentions the presence of active peristalsis during spinal anæsthesia, but, as Dr. A. L. Flemming pointed out at the meeting, this is also observed when the patient is under a general anæsthetic. In the light of recent work by M'Crea and Macdonald[5] of Manchester University, the old theory of the vagus being the excitor and the splanchnic the inhibitory nerve of the stomach is no longer entirely tenable. It is probable, then, that Dr. Kelly's explanation—that the increased peristalsis is due to paralysis of the "vasomotor nerves (the source of intestinal inhibition)"—is more in accordance with an old theory than with new truth.

If, then, the Pitkin method gives little control over the duration of the anæsthesia, less over its height, and practically none over the blood pressure, and if Dr. Kelly's explanation of the increased peristalsis is at variance with the results of modern research into the function of the splanchnics, in what does the excellence of the method consist? Insufficient experience of other methods and of the limits to which the Pitkin method can be pushed make me diffident of too great a dogmatism. However, I would suggest that safety is its primary virtue. In novocain we have a drug that is almost if not quite ideal. Stovaine is admittedly more toxic than novocain, but it causes greater muscular relaxation. The muscular relaxation given by novocain is obviously not that of curare. In a high abdominal operation it is usual to cause some discomfort on manipulation of the stomach, and this is commonly attributed to dragging on the peritoneum on the under surface of the

---

[5] M'Crea, E. D., and Macdonald, A. D.: Quart. Jour. Exper. Physiol., 1928, xix., 161.

diaphragm or to vagal stimulation. This is thought to be unavoidable because if the anæsthetic went high enough to anæsthetise the third and fourth cervical segments it would paralyse the diaphragm. I doubt this. First, Pavlov has shown that the "motor area" in the brain is primarily a receptor rather than an executor area, and there may be an analogous mechanism in the cord. Secondly, in a very high anæsthesia, up to and even beyond the first dorsal, there is no clinical evidence of interference with the intercostal muscles. Presumably the relaxation of the abdominal muscles under novocain is due to a paralysis of the receptor mechanism, and, even if this paralysis extended to the third and fourth cervical, the diaphragm would still receive innervation from the unparalysed respiratory centre and exercise its still unparalysed motor mechanism. In other words, novocain is a drug that paralyses receptors only. This would be as fatal to the diaphragm as to the abdominal muscles were it not for the alternative stimulus for the diaphragm from the respiratory centre. It is somewhat like an engine with dual ignition; when the battery fails it will run on the magneto.

The next point in favour of the Pitkin method is the use of a colloid which tends to hold the solution together and delays absorption of the drug. This reduces toxicity and, allowing the use of larger doses, prolongs the duration of the anæsthesia. There is no evidence to show that "gliadin," whatever it may be, is any better than dextrin. Dr. Pitkin is too much of a purist to admit that there is any virtue in chloroform, but I have found that a mixture of the two methods can be made to combine the advantages of each without the drawbacks of either (Fig. 5).

The measure of success achieved with spinal anæsthesia depends on the trained intelligent coöperation of those surrounding the patient. A nurse who tells her patient that nothing would induce her to have a spinal anæsthetic goes some way towards inducing a wrong state of mind which makes all subsequent procedures more difficult. Conversation, however necessary it may be, if conducted in whispers is apt to give rise to the impression that some sort of conspiracy is afoot. The surgeon and the doctor in attendance should trust the anæsthetist, whose job it is to keep in intimate touch with the patient in order to be aware of the exact state of his feelings. It is the surgeon's part to get on with the operation and glean such information as he may require from the anæsthetist and not from the patient. In testing for the height of anæsthesia a surgeon should not clip the skin with towel forceps and say "Does that hurt you?" It is rude to the anæsthetist and disturbing to the patient; it is apt to shake his confidence, and he will argue that these people do not know whether they are hurting him or not so he had better let them know in time. Another thing patients resent—two of them have used the word "insulting" when referring to it—is the placing of instruments on their undefended chests. No one but an anæsthetist, whose hand frequently wards off some of this steady rain of blows, knows how exactly the adjective describes the offence.

FIG. 5.

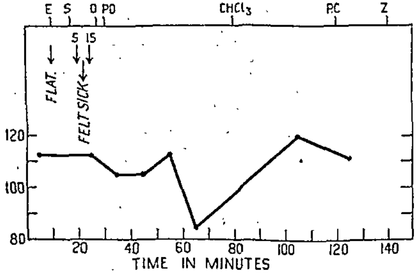

Chart of blood pressure in case described in text. E. = 2 c.cm. ephedrine, 5 per cent.; novocain, 1 per cent. S = 3 c.cm. spinocain. O = Operation begun. P.O. = Peritoneum opened. P.C. = Peritoneum closed. Z. = Operation finished. Flat 5 and 15 = degree of slant of table with head down.

Whatever success we may have achieved with spinal anæsthesia has been due to the coöperation of all concerned. The development of a new technique calls for the exhibition of many desirable qualities and they have been forthcoming. The enthusiasm of Mr. A. H. Burgess, the interest of Mr. W. H. Hey, and their patience, coupled with the loyalty of their nursing staffs, have been indispensable and inestimable.

THE IRRADIATION OF MILK

FOR THE INCREASING OF ITS ANTIRACHITIC POTENCY.

BY DAVID NABARRO, M.D., F.R.C.P. LOND.,
DIRECTOR OF THE PATHOLOGICAL DEPARTMENT, THE HOSPITAL FOR SICK CHILDREN, GREAT ORMOND-STREET;
AND
J. O. HICKMAN,
BARRISTER AT LAW.

With a Description of a Method of Irradiation Devised by J. O. HICKMAN.

IT has been known for some years that the antirachitic potency of milk could be greatly increased by irradiation from a quartz mercury-vapour lamp (Steenbock and Daniells,[1] 1925), but it soon became evident that such treatment, while beneficial from the standpoint of the vitamin D content, could be extremely harmful from the standpoint of the vitamin A content (Titus,[2] &c., 1926, and Drummond,[3] 1927). The treatment which resulted in the destruction of vitamin A appears, however, to have been unnecessarily prolonged, for later work by Supplee and Dow[4] (1927) claims that an exposure of milk in thin films to a Hanovia lamp for a few seconds or not more than one minute about doubles the antirachitic value of the milk, and apparently does not destroy the vitamin A.

Earlier investigations showed that a prolonged exposure imparted to the milk a disagreeable odour and taste, and one of us (J. O. H.) has found that any time longer than eight minutes turns the milk putrid; a series of tests has shown that a slight change in flavour could not infrequently be detected after an exposure of 30 seconds, which became more marked with every lengthening of the exposure till the change to putridity after eight minutes.

The present paper gives the results of short-time exposure of milk (both whole and skimmed) to ultraviolet light under conditions which have definitely increased the antirachitic potency without apparently decreasing the vitamin A content of the milk or appreciably affecting its taste. The irradiation of the milk was carried out daily by a method devised by one of us (J. O. H.). The milk was run over a 21 in. by 22 in. milk cooler at the rate of a gallon in 15 minutes. It was allowed to run for a few minutes before the lamp was brought to work on it, during which time the film was spread evenly over the whole surface with a spoon. Once spread the film should not break. The lamp used was of the Hanovia type. It was run at 200 volts, 2 ampères, and allowed to burn for several minutes before it was allowed to play on the milk. It was hung at a distance of 12 in. from the middle of the film of milk, and a specially designed reflector to focus the rays upon the surface to be treated was employed. It may be estimated that a particle of milk would be, on an average, 30 seconds on the cooler, but for a great part of this time it would be on the horizontal parts of the cooler, and thus scarcely affected by the rays from the lamp. No special efforts were made to produce a current of air between the lamp and the film of milk. For the purpose of the fourth experiment the rate of flow of the milk was accelerated so that the time of exposure was reduced to about 15 seconds and two gallons passed over the cooler in 15 minutes. The sample of untreated milk was taken from the bucket of milk which was afterwards treated, so that the two samples "treated" and "untreated" were identical except for the irradiation.

It was felt to be of the highest importance that no treatment of milk should be recommended if there were the slightest danger of any reduction in its vitamin A activity. Accordingly a rigorous test of the vitamin A content of the milk before and after the irradiation was carried out by the method described by Steenbock and Coward[5] (1927).

Experimental Work.

Controlled tests of the vitamin content of the irradiated milk have been made for us on rats, with the following results:—

Vitamin A.—Varying quantities, 0·5, 1 and 2 c.cm., of the untreated and of the irradiated milk was given each to three or four rats. The growth response of the rats was graded to the dose in each case, and there was no appreciable difference between the growth response of the rats given untreated or irradiated milk; therefore it appeared that the vitamin A content of the milk was unaffected.

Vitamin D.—As to the vitamin D content of the milk irradiated, five tests were carried out between August, 1928, and June, 1929; in each the rats were given the high-calcium, low-phosphorus diet of Steenbock and Black[6] (1925) for a preparatory period of three weeks; thereafter some rats in each litter were given a preparation of irradiated ergosterol, some untreated milk and some irradiated milk, in each case for a period of ten days; the degree of healing engendered in the rachitic rats was estimated by the "line" test.

Expt. 1 (August, 1928).—To compare the effects of untreated milk, irradiated milk, and irradiated ergosterol. The irradiated milk was found to contain 0·13 to 0·2 unit of antirachitic activity per c.cm., or more than five times that of the untreated milk.

Expt. 2 (November, 1928).—To compare the effects of untreated milk, milk irradiated once and twice, and irradiated ergosterol. The once irradiated milk contained 0·5 unit of antirachitic activity, and the twice irradiated about double this or one unit: the antirachitic activity in the untreated milk was negligible.

Expt. 3 (February, 1929).—To determine whether skimmed milk could be given antirachitic properties by irradiation. The severity of the rickets in the rats used for this test was distinctly less than in the previous tests, but it showed that the untreated skimmed milk had no antirachitic activity, but the irradiation of this milk produced appreciable antirachitic activity in it. In all the above experiments the time of exposure of the milk was 30 seconds.

Expt. 4 (February, 1929).—To compare the capacity for activation of whole and skimmed milk, and to try the effect of the shorter exposure of 15 seconds only. The result showed that the vitamin D content of the untreated milk was nearly negligible, but the irradiated skimmed milk contained 0·8 unit of antirachitic activity per c.cm., and the irradiated whole milk 2 units per c.cm.

Expt. 5 (June, 1929).—To estimate the antirachitic potency of the milk of cows on the best summer feed and to try the effect of an irradiation for eight seconds only. The untreated milk contained 0·1 unit of antirachitic activity per c.cm., which the irradiation for eight seconds increased to 1 unit, an increase of no less than 900 per cent.

Results on Children.

Three examples of the use of this irradiated milk over a period of time can be given (J. O. H.).

(*a*) Boy born Oct. 2nd, 1922:

	1/1/27	1/1/28	1/1/29	2/11/29	2/12/29
Height.	3ft. 8⅝in.	3ft. 10in.	4ft. 2¼in.	4ft. 4¼in.	—
Weight.	41lb. 9oz.	44lb. 14oz.	50lb. 2oz.	57lb.	58lb. 4oz.

(*b*) Girl born Jan. 18th, 1924:

	1/1/27	1/1/28	1/1/29	2/11/29	2/12/29
Height.	3ft. 2⅜in.	3ft. 4½in.	3ft. 8¼in.	3ft. 10⅝in.	—
Weight.	32lb. 8oz.	33lb. 1oz.	37lb. 2oz.	41lb. 13oz.	42 lb.

These children had untreated milk in 1927, and from January, 1928, to date the same quality milk irradiated; the average quantity taken by the boy was 2 pints per diem, by the girl 1½ pints per diem.

(*c*) Boy born July 3rd, 1927:

	Weight.	
Aug. 2nd, 1928	20lb. 4oz.	on ordinary Grade A milk.
Sept. 2nd, ,,	20lb. 9oz.	
Oct. 2nd, ,,	21lb. 7oz.	half the month irradiated milk.
Nov. 2nd, ,,	21lb. 13oz.	on ordinary milk.
Dec. 2nd, ,,	24lb.	on irradiated milk.

Thereafter he continued on the irradiated milk to gain on the average 1 lb. 4 oz. per month for three months.

Discussion.

The increase in the weight of these children when given irradiated milk, compared with that when they were given the same milk but untreated is striking. Observations have also been made (D. N.) at the Hospital for Sick Children, Great Ormond-street, on children with severe rickets, marasmus, malnutrition, and other serious ailments, with very good results, although it is not possible to give to these observations the scientific accuracy described for the animal experiments detailed above. It was frequently found that a week or two on the irradiated milk acted as a fillip to the child, who then started to improve, after having been stationary for some time. The writer has drunk a glass of the milk daily for more than a year, and during the past winter, when on several occasions a tickling in the throat seemed to be the premonitory sign of a threatening cold, this did not materialise. Several adults who have partaken of the milk daily for many months feel themselves the better for it.

There is a further point of interest in connexion with the irradiation of milk—viz., the effect on the bacterial content. Many examinations of the bacterial content before and after irradiation have been made and invariably there has been a considerable reduction in the numbers of bacteria present after the irradiation, frequently to only one-tenth of the original numbers. It should be added, however, that this milk is amongst the most bacteria-free examined (D. N.), for rarely have there been more than a few hundred organisms per c.cm. of the untreated milk, and on no occasion have more than 4000 organisms per c.cm. been counted. This purity of the milk as regards bacteria may possibly be due in part to the practice of applying the ultra-violet rays to the udder and teats of the cow just before milking, and to the fact that all the dairy utensils are similarly treated just before use.

In a recent paper on the therapeutic value of irradiated milk in the treatment of rickets, Chalmers Watson, Finlay, and King[7] confirm earlier observations as to the value of irradiated milk in the prevention and cure of rickets, and they show that the disease is cured more quickly and economically by the use of irradiated milk than by the various irradiated preparations on the market. Their paper confirms our own observations that irradiated milk may prove of considerable value in the treatment of other disorders besides rickets. They strike a note of caution, however, which should be borne in mind when irradiated milk is being given to children—namely, that in view of its powerful effect on the growing bones, the possibility of their premature ossification must not be overlooked, and they advise that irradiated milk should not form the sole diet of infants and children, but that these should be given one part of irradiated milk to one or two parts of good, fresh milk.

More recently still Katharine Coward,[8] in an article on the value of irradiated milk compared with cod-liver oil as a source of vitamin D, draws attention to the fact that vitamin D content of irradiated milk may vary within wide limits (0·1 unit to 2 units per gramme), though with the method of irradiation we have described the usual content of the milk has been about 1 to 2 units per gramme. Dr. Coward also points out that cod-liver oil itself may vary from 50 to nearly 200 units per gramme as regards its vitamin D content.

Summary.

1. Untreated milk, both whole and skimmed, has very little antirachitic activity. The best sample examined had only 0·1 unit per c.cm., and this was taken during a time when the cows were receiving the best "summer feed." Three samples taken during the winter and one taken during drought conditions at the same farm showed such slight antirachitic potency that it might be termed negligible.

2. The antirachitic potency of the milk can be increased enormously by direct irradiation from a quartz mercury-vapour lamp. Where the potency of the untreated milk could be measured, that of the treated milk was increased nine times by an exposure of eight seconds.

3. The capacity for activation of different samples of milk varies.

4. An exposure of 30 seconds (the longest period tried in these experiments) had no detectable influence on the vitamin A potency of the milk.

5. The irradiated milk can cure as well as prevent rickets in children and animals, and is of value in other disorders of nutrition, and in other diseases.

6. Irradiation produces a marked decrease in the bacterial content of the milk.

TREATMENT OF
STREPTOCOCCAL SEPTICÆMIA WITH STREPTOCOCCAL ANTITOXIN.

BY A. B. ROSHER, M.R.C.S. ENG., D.P.H.,
DIRECTOR OF THE CHARING CROSS HOSPITAL INSTITUTE OF PATHOLOGY.

Mr. Burt-White's recent paper[1] on the treatment of cases of puerperal septicæmia by scarlet fever antitoxic serum has prompted me to publish, rather prematurely, a very small number of cases of streptococcal septicæmia which have been successfully treated in this manner.

I intend to publish only the four cases in which the infection was proved by isolation of *Streptococcus hæmolyticus* from the blood, but as they were all extremely severe, and as they all made complete recovery, I think it worth placing them on record with the hope that this form of treatment may receive a more extensive trial. These cases were in no way selected and happen to be the only ones that I have had access to since the publication of the experimental work of Parish and Okell[2] in 1928. This important piece of work made it probable that antitoxin prepared from scarlet fever streptococcal toxin would be effective against hæmolytic streptococci from other sources, and they urged that "as this is the only streptococcal antibody with any acceptable and experimental credentials it should be given an extensive trial in all severe streptococcal infections, particularly in general septicæmia."

Historical.

The published results of the antitoxin treatment must necessarily be scanty at this early stage and, apart from the paper referred to above, I am only aware of the following:—

Sanderson[3] and others in 1927 successfully treated a case of puerperal septicæmia and a case of septicæmia secondary to otitis media by injecting concentrated scarlatinal streptococcal antitoxin intramuscularly. These cases were first tried with the ordinary polyvalent antistreptococcal serum, but as they did not respond to this and other remedies the scarlet fever streptococcal antitoxin was administered. The second case was thought to be beyond hope of recovery when the antitoxin treatment was commenced. Boente[4] in the same year, 1927, reported that the serum from convalescent cases of scarlet fever had a curative action in cases of erysipelas and other streptococcal infections, but no effect in cases of infection with *B. coli* or *Staphylococcus aureus*. He also showed that antiscarlatinal serum from an immunised horse was beneficial in cases of puerperal infection, acute tonsillitis, and erysipelas, and furthermore, that sera prepared against strains of streptococci isolated from cases of puerperal fever or erysipelas were beneficial in scarlet fever.

Cases.

The following is a brief description of the cases under my observation.

CASE 1. *Septicæmia following a Pricked Finger.*—On May 14th, 1928, a doctor, aged 69, pricked his thumb with an adenotome after operating on a case of tonsils and adenoids. A few days later the thumb became very painful and slightly œdematous, and an unsuccessful attempt was made to reach the pus under a local anæsthetic. The infection started to spread up the arm, and on May 21st temperature rose above normal. On the 22nd the temperature was 103° F., a general anæsthetic was administered, and Mr. E. K. Martin performed an extensive operation evacuating the pus. A blood culture taken at the time of operation gave a pure and massive growth of *Streptococcus hæmolyticus*. 15 c.cm. of scarlet fever streptococcus antitoxin (Parke, Davis and Co.) were injected intramuscularly. On the 23rd the temperature reached 103° F., and another 15 c.cm. of the same antitoxin were administered subcutaneously. On the 24th the temperature only reached 100° F., and 10 c.cm. of concentrated scarlatina streptococcus antitoxin (Burroughs, Wellcome and Co.) were administered subcutaneously. On the 25th the temperature only reached 99° F., and a blood culture taken on this date was sterile. A further 10 c.cm. of antitoxin (B. W. and Co.) were injected subcutaneously. On the 26th the temperature did not rise above 99° F. Thus for two days the temperature was practically normal, but the next day and during the following ten days it rose and fluctuated daily on the 101° F. mark. This was due to the pus pocketing, and when the pockets were opened the temperature became normal and the patient recovered. The patient's general condition was so good during the second febrile period that no further serum was given.

CASE 2. *Puerperal Septicæmia.*—A woman, aged 37, was confined on April 2nd, 1929, the child being born before arrival of the doctor. No manipulation was employed. She was quite well until the third day when the temperature rose to 101° F. and pulse-rate to 116. From this until the eighth day the temperature varied between 104·2° and 100·8° F., with a pulse-rate of 150–120. General peritonitis was suspected and a laparotomy was performed, but apart from a little serous effusion nothing was found. A blood culture was performed and *Streptococcus hæmolyticus* was isolated. When seen by Mr. C. D. Read she was in extremis, with heliotrope flush and slight toxic strabismus. 10 c.cm. of scarlatina streptococcus antitoxin (B. W. and Co.) were given intravenously at once and 10 c.cm. intramuscularly on the thirteenth and fourteenth days respectively. On the fifteenth day the temperature was 99·2° F. and pulse-rate 112, and the patient was definitely better. The serum was repeated two days later and the temperature gradually settled down and the patient made a complete recovery.

CASE 3. *Puerperal Septicæmia.*—A woman, aged 29, was confined on Sept. 1st, 1929. The confinement was normal apart from a small perineal laceration. After the confinement the temperature was about 99° F. until the fourth day when it reached 100° F. On the seventh day the temperature was 102·2° F., with a pulse-rate of 96, and a foul, blood-stained vaginal discharge; the uterus was not involuted. On Sept. 8th the uterus was evacuated and a cotyledon of placenta was removed. As a result of this the temperature showed slight improvement but soon rose to the 103° F. and 104° F. mark, and signs of general septicæmia appeared. *Streptococcus hæmolyticus* was isolated

A CASE OF
LANDRY'S PARALYSIS OF DESCENDING TYPE.

BY F. E. SAXBY WILLIS, M.C., M.D., M.R.C.P. LOND.,
PHYSICIAN TO THE HAMPSTEAD GENERAL HOSPITAL, ROYAL CHEST HOSPITAL, AND TO THE WEIR HOSPITAL, CLAPHAM PARK;

AND

J. W. F. JEWELL, M.D., M.S. LOND.,
CONSULTANT TO THE WEIR HOSPITAL.

With Pathological Note by

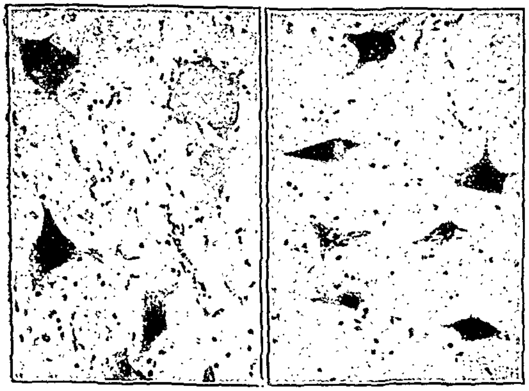
DR. J. G. GREENFIELD, *and* DR. NORAH SCHUSTER.

THIS case warrants description as an example of Landry's paralysis, confirmed by histological examination, and showing clinically the unusual feature of onset in the upper extremities.

The patient, a cashier, aged 43, was first seen by one of us (J. W. F. J.), on May 5th, 1927. She complained that while trying to pick up a bag of money with her left hand she had noticed a sudden loss of power in the left hand and arm. She had finished the day's work, using her right hand only. When seen in the evening the grip of the left hand was extremely weak, the right hand being normal. On May 6th the grip of the right hand became impaired, and in the course of the next two days the right arm became as weak as the left; there was practically complete paralysis of both arms. On May 10th weakness of both legs developed; this gradually increased up to the 13th, when she was seen by us both in consultation, and it was decided to move her *to the Weir Hospital.*

The *previous history* had been good, apart from chronic constipation. A few weeks before the onset of this illness she had had an "influenzal cold," and from the time she first came under observation it was noted that she had nasal catarrh, and a cough with scanty expectoration.

FIG. 1. FIG. 2.



Sections from spinal cord at level of the fourth lumbar vertebra (Fig. 1) and from hypoglossal nucleus (Fig. 2); some of the cells show achromatosis and some are normally stained

On admission to hospital she looked quite well in herself, and, apart from the excessive weakness of all the extremities, made no complaint of pain or other subjective symptoms. There was, however, extreme constipation and difficulty in micturition. On catheterisation 32 oz. of urine were withdrawn. The tongue was thickly coated, the fauces were injected, and muco-pus was seen in the pharynx. The cardiovascular system was normal. Râles were heard at the bases of both lungs. The abdomen was noticeably distended.

Examination of the central nervous system revealed no abnormality of the cranial nerves. The upper extremities were in a state of complete flaccid paralysis below the shoulder. Tendon jerks were only obtained with great difficulty, with the arm supported in the optimum position. Cutaneous sensations and muscle pain sense were present and normal. The lower extremities showed a similar condition of complete flaccid paralysis with normal sensation; tendon reflexes were obtained with difficulty, but the plantar response was flexor. Electrical reactions showed no response whatever to faradic current (Stuart and Bristow coil). Her temperature was 97·8° F., pulse-rate 72, and respiration-rate 20.

Lumbar puncture was performed, but revealed no obvious increase in pressure. The fluid was clear with no excess of albumin; the globulin test for excess was positive, slight opalescence appearing with ammonium sulphate. The sugar content was normal. A diplobacillus was present in the deposit, but was probably a contaminant. A cell count was impossible owing to delay in transit.

During the next three days the temperature rose to 100° each evening, and there was an increase of cough. On May 19th breathing became laboured, owing to interference with the diaphragmatic movements, and tubular breathing was heard at the left base. At 5.30 on May 20th the patient suddenly collapsed and died. Half an hour previously she had been perfectly conscious and in no pain.

Autopsy by Dr. Norah Schuster (Report on Specimens Received).

The specimen of lung showed broncho-pneumonic consolidation. The spleen was congested, but cultures from the pulp were sterile.

Sections of the spinal cord and peripheral nerves were stained by the following methods: (*a*) Sharlach R. (*b*) Hæmatoxylin. (*c*) Van Gieson. (*d*) Marchi's method for demonstrating degeneration (Nissl's nerve-cell stain).

Dr. J. G. Greenfield examined the sections in this case, sent to him by Dr. Schuster, and reported as follows.

Note by Dr. J. G. Greenfield.

"The changes present in the cord are those which have been constantly described in Landry's paralysis—i.e., chromatolysis of anterior horn cells and congestion of vessels. There was no evidence of degeneration in the emerging nerve-fibres, as shown by Marchi's method; in fact this stain revealed only the lipochrome in the nerve-cells, which was in slight excess of the normal.

"The vascular congestion appeared to affect the small veins chiefly, and the capillaries were not greatly distended. It is possible that it should be related rather to the dyspnœa from which the patient suffered than to a local congestion of the vessels of the cord. Many of the small veins contained very numerous leucocytes in addition to red blood corpuscles, and some were almost packed with these cells, but there was no evidence of thrombosis. At the level of the first thoracic segment there was a small hæmorrhage into the anterior horn, which must have taken place at least some hours before death, as the neighbouring nerve-cells contained dark doubly refractile granules which probably consist of hæmatin or some early decomposition product of hæmoglobin., There was no sign of lymphocytic infiltration either of the meninges or grey matter.

"Chromatolysis of the central type (axonal reaction) was most conspicuous in the large ventral horn cells of the lumbar enlargement. Here it affected almost every cell in varying degree, although at each level one or two normaly staining cells could be seen. The most affected cells were uniformly pale, and their nucleus was eccentric and subcapsular, and often presented an irregular outline.

"In the cervical enlargement also the majority of the cells had undergone a similar change, but in the thoracic region of the cord only one or two cells at each level were affected. In the hypoglossal nucleus and the nucleus ambiguus, similarly, the majority of the cells were normal and only a few cells presented minor degrees of chromatolysis. As a general rule the largest cells seemed to be more severely diseased than the smaller ones, although this appearance may have been due in part to the swelling which the cells had undergone in the process of chromatolysis. Vacuolation of the cell body was never seen. The cells of Clarke's column and those in the dorsal nuclei of the medulla appeared to be quite normal.

"The pathological examination therefore confirms the diagnosis of Landry's paralysis, which may be defined as an acute neuronitis limited to the lower motor neurones. There was no sign of inflammation apart from the vascular congestion which, as has been suggested, may have been due rather to back pressure than to local inflammation."

The diagnosis of Landry's paralysis in this case is founded on the following features: (1) The acute onset and rapid spread of a paralysis involving all the limbs and (terminally) the phrenic nerve. (2) The absence of sensory disturbance. (3) The demonstration in post-mortem sections of the spinal cord and peripheral nerves of an acute degeneration of the horn cells, and of the myelin sheaths, with no inflammatory reaction. The case presents unusual features in that clinically the paralysis was descending and not ascending; Church and Peterson describe two cases of this type. The post-mortem findings support the view originally put forward by Spiller that the toxic agent, whatever it may be (in this case apparently an acute nasal infection), acts on the lower motor neurones as a whole. Landry's paralysis is a rare disease. Only 16 published cases are on record in the last ten years, and in the majority post-mortem confirmation has been lacking.

ON THE

TRANSMISSION OF MAMMALIAN NEW GROWTHS BY FROZEN MATERIAL.

BY W. CRAMER, D.Sc. EDIN., PH.D. BERLIN, M.R.C.S. ENG.

(From the Imperial Cancer Research Fund.)

NUMEROUS experiments have been carried out in the past to determine whether mammalian tumours can be transmitted without the intervention of living cells. It was found that the inoculation of cells which had been killed by heat, radium, freezing, or mechanical disintegration gave negative results. Similarly, the injection of cell-free watery extracts of mammalian tumours has yielded negative results, except in the hands of one investigator. In the course of repeating these experiments the injection of watery extracts has given uniformly negative results in hundreds of experiments, if the absence of living cells was ensured by filtration through a porcelain filter, or by spinning and careful removal of the upper layer of the supernatant fluid. On the other hand, the inoculation of material obtained from six different strains of mammalian tumours by a course of repeated freezing and thawing has yielded in one strain a large number of positive results—73 positive results in 209 inoculated mice. This strain is the rapidly growing sarcoma 37 S. strain of the Imperial Cancer Research Fund. Three different rapidly growing carcinoma strains—Nos. 63, 91, 113—gave uniformly negative results. Experiments in the past in which negative results were obtained after freezing or mechanical disintegration were carried out with transplantable carcinomata. Two other rapidly growing sarcoma strains—the Jensen rat sarcoma and the Crocker mouse sarcoma—gave only a very low percentage of positive results, differing widely in this respect from the sarcoma strain 37 S. Thus the Jensen rat sarcoma gave five positive results in 102 inoculated mice; the Crocker sarcoma nine positive results in 79 inoculated mice. The tumours arising by inoculation of frozen material were always identical with the tumours from which the material was obtained. The positive results are not evenly distributed over the successive experiments. Thus, in the strain 37 S. with an average of 35 per cent. of positive transmission, half the experiments gave completely negative results, while the other half gave positive results in a very high percentage varying from 50 per cent. to 100 per cent., with an average of 70 per cent. After two hours' incubation of frozen material of 37 S., which by itself gave a high percentage of positive transmission, the property to transmit the tumour was either greatly weakened or completely abolished.

All attempts to obtain living tissue cultures from material subjected to the same treatment of repeated freezing and thawing have given negative results. Experiments carried out by Mr. H. G. Crabtree show that, contrary to statements in the literature, respiration and glycolysis do not completely disappear after repeating freezing and thawing. They are only greatly diminished. In this respect, however, no difference was observed between the cells of the sarcoma strain 37 S. on the one hand, and normal cells or the cells of the carcinoma 63 on the other, except that the diminution was much greater for malignant cells than for normal cells. The results may be summarised as follows:—

—		Tissue culture.	Metabolism.	Transmission.
Normal cells ..		Negative.	Present but diminished.	..
Carcinoma ..		"	Present but greatly diminished.	Always —
Sarcomata	J. R. S.	"		Rarely +
	Crocker	"		Rarely +
	37 S.	"		Frequently +

The interpretation of these results depends on what we accept as the criterion of death. If the failure of frozen material to live and grow when cultured in vitro is accepted as evidence that all the cells have been killed, then the results would demonstrate the transmission of at least one strain of a mammalian tumour without the intervention of living cells. The persistence of respiration after freezing and thawing is not necessarily evidence of the survival of a few cells, since in that case the tissue culture experiments should have given positive results and the transmission of the frozen carcinomata should also have given positive results, at least occasionally. The persistence of respiration may merely indicate that the process of repeated freezing and thawing, while destroying the structure of the cell, has left behind protoplasm in which the enzymatic processes of respiration and glycolysis are still proceeding.

On the other hand, it may reasonably be argued as an alternative explanation that the successful transmissions with frozen tumour material are due to the survival of a few living cells. Such an explanation is, however, not without difficulties. If that explanation is adopted one must assume that the sarcoma cells of strain 37 S. are more resistant to the lethal effect of repeated freezing than normal cells, the cells of carcinomata, and even the cells of the two other sarcoma strains investigated. One would further have to assume that the resistance of the cells of sarcoma 37 S. shows considerable variation at different times. As stated above, the quantitative measurements of respiration and glycolysis of frozen material give no indications of any such differences. The absence of all manifestations of life in the tissue culture experiments is also difficult to reconcile with such an explanation.

Since no direct evidence seems available by which this question can be decided it will be necessary to collect and consider circumstantial evidence, such as, for instance, the very evanescent nature of the property of frozen material (destruction by incubation for short periods) on which the power to transmit tumours depends. In any case it is justifiable to point out that until the successful transmissions with frozen material are satisfactorily accounted for as being due to a survival of living cells, the axiom of the non-transmissibility of mammalian tumours without the intervention of living cells is open to doubt.

A detailed account of the experiments on which this short communication is based will be published later.

THE QUEEN'S HOSPITAL, SIDCUP.—We have already announced that this hospital has been purchased by the London County Council for use as a general institution for post-operative cases. The hospital was built in 1917 in the grounds of Frognal House, the residence of the late Earl Sidney, for the treatment of facial and jaw injuries. Between August, 1917, and May 31st last year 18,135 patients were received; the facial cases included 714 officers and 8035 other ranks, and the major operations numbered 11,752.

Medical Societies.

ROYAL SOCIETY OF MEDICINE.

SECTION OF PSYCHIATRY.

AT a meeting of this Section held on Jan. 14th the chair was taken by the President, Sir ROBERT ARMSTRONG-JONES, and Dr. MACDONALD CRITCHLEY read a paper on the

PATHOLOGY OF THE SENILE PSYCHOSES.

The modern histological conception of the senile psychoses dated, he said, from the last decade of the nineteenth century, when Alzheimer had sharply distinguished arterio-sclerotic dementia from senile dementia. The distinction was of more theoretical than practical importance, as the cerebral arteries usually shared in the senile changes, though how far they influenced them was quite unknown.

The brain of healthy old age—if there were any such thing—showed a certain amount of atrophy with widening of sulci, reduction in weight, ventricular distension, thickening of the meninges, and sclerosis of the basal arteries. There was a disappearance of a number of nerve cells from the cortex, especially the frontal and prefontal regions, and from the basal ganglia, locus niger, and olives. The cells remaining might show fatty degeneration—the most constant feature—or the intracellular fibrillary tangles of Alzheimer, which varied from simple intensification of the fibrillary network to the reduction of the cell to a mere skeleton made up of tangled densely staining coils. Some believed these structures to be neuroglial, but most authorities regarded them as neurofibrillary. Bouman had drawn attention to a peculiar spindle- or torpedo-shaped swelling of the proximal portion of the axones of the Purkinje cells; the interior was homogeneous, but the periphery was reticular, and vacuolation might occur later. Disappearance of the neurone led to relative demyelinisation, which was most marked in the tangential fibres. Regressive glial changes took the form of a diffuse subpial, subependymal and perivascular gliosis, with frequent monster cells and reticulation. Regressive glial changes included the appearance of rod cells, especially in the molecular layers of the cornu ammonis, mucocytic degeneration of the oligodendroglia, and an increase in the amount of protoplasm in the microglial cells. The neuroglial changes in the cerebellum were essentially patchy, the gliosis being limited to the perivascular zones, the depths of the fissures, the white matter round the dentate nuclei, and the neighbourhood of the Purkinje cells.

The combination of diffuse gliosis with neuronal atrophy led to shrinkage and loss of weight, and hydrocephalus ex vacuo. The shrinkage was often most marked in the regions of the loci perforati posticus and lateralis, where the brain substance fell away from the basal arteries and caused wide perivascular dilatation.

Depositions in the senile brain included corpora amylacea, which appeared especially in the fimbria and round the blood-vessels, but which never aggregated, and senile plaques in the cortical grey matter. These plaques varied in form, but rings, radial figures, stars and discs were common, and there was often an amorphous or cellular nucleus, containing some amyloid-like substance. Sometimes the plaque contained lipoid, but the fatty plaques of Laignel-Lavastine and Tinel were regarded by Rizzo as artefacts. Microglia played a rôle in the formation of plaques, and neurofibrils and sometimes myelinated axis-cylinders were seen. Plaques were now usually regarded as a special type of tissue reaction directed against a specific and toxic metabolic process. A primary involutional alteration in the chemistry of the fundamental ground substance was believed to cause depositions of lipoid or amyloid material in the nervous system; these precipitates were strongly argentophil. They provoked a microglial reaction, and Hortega cells became incorporated in the innermost part and then underwent degeneration. It was doubtful whether plaques often occurred in the absence of psychical change during life.

There was a lack of certain knowledge as to the extent and relative frequency of the various histological changes in the senile brain. The common findings were diffuse fatty degeneration, a moderate degree of atrophy of nerve cells, and glial proliferation.

The Senile Dementias.

The change in senile dementia was in most cases an exaggeration of the histological processes seen in the healthy senile brain; there was no abrupt line of demarcation. This intensification might be selective. Dementia senilis simplex was characterised by an abundance of plaques, especially in the frontal and temporal regions; they might even be found in the central grey matter, the pons, the mid-brain, the cerebellum, and the spinal cord. It was not possible to distinguish the brain of a depressed senile dement from that of an agitated or a confused one. In Pick's disease there was marked localised neuronal atrophy, without any of the other changes except moderate secondary gliosis. The numerical atrophy was most obvious in the three upper cell laminæ of the cortex, and caused convolutional atrophy with widening of sulci. The change was usually symmetrical and often limited to the frontal, temporal, or occipital lobes. There was no explanation of the peculiar distribution. Alzheimer-Perusini's disease was characterised by a preponderating change in intracellular fibrils. The pathology of presbyophrenia had not been determined with certainty; recent studies tended to associate its pathological picture with that of Alzheimer's disease. Claude and Lhermitte had described a diffuse atrophic cortical sclerosis which was distinguished from simple dementia by a preponderating overgrowth of neuroglial fibrils, especially in the cortex. Probably there were other varieties of senile psychosis as yet unidentified. Clinical and pathological phenomena must be correlated with caution. The chemical and physical reactions of nerve tissue to various dyes were at best a very rough measure of the functional integrity of that tissue during life, and the presence of scarred or degenerated structures in the brain had not necessarily any connexion with signs or symptoms observed during life. Pathological findings were the outward signs of a particular type of tissue-reaction to some factor which was the basis of both clinical and pathological anomalies. Simchovicz had pointed out that the brain of a young senile dement was histologically indistinguishable from that of a normal centenarian, but the clinical pictures were widely different. According as the nature of the outside agent varied, so the cerebral histological reaction altered. The common features of senile psychoses were also found in very different conditions—e.g., swelling of the Purkinje cells in disseminated sclerosis, cerebellar atrophies, juvenile paralysis and schizophrenia, and senile plaques in Korsakow's psychosis and tabes. Some parts of the nervous system might be endowed with limited viability and be doomed to die before the rest of the system. Idiopathic Parkinson's disease was a senile process limited to the paleo-striatum; Jakob's senile rigidity showed plaques and other senile lesions in the corpus striatum; and in delayed cortical cerebellar atrophy the signs of progressive cerebellar dysfunction were linked with an atrophy of the paleo-cerebellum. There was urgent need for fuller information about senile cases, and for judicious correlation of clinical and pathological findings.

Discussion.

The PRESIDENT spoke of the difficulty of delimiting senility from the normal. The first function to decline in senility was recent memory; the nouns went first, then the adjectives, and finally the verbs. In premature senility the new engram might become obfuscated before the age of 40. Next came indifference to ceremonies and courtesies, ending in serious lapses. Cannon had shown that the effects of fear included marked changes in the Purkinje cells. Heredity had very little to do with the age of onset of senility. Moral habits were the first to go; the natural affections also became loosened and might be replaced by hatred. A peculiar characteristic was penuriousness or miserliness. Old people should not be sent to almshouses; they became much worse as the result of cutting off environmental stimuli. They should stay at the hearth among their grandchildren.

Dr. Kingston Barton emphasised the importance of memory, especially from the point of view of the general practitioner. There must be some change in the brain associated with the loss of memory. Remarkably few people over 65 escaped all the changes characteristic of senility.

Dr. A. G. Duncan said that the only constant biochemical indication of the metabolic changes of senility was the great increase in blood cholesterol, and asked whether this could be associated with the formation of plaques.

Dr. R. M. Stewart referred to the constant senile increase of cerebro-spinal fluid, which he believed to be proportional to the atrophy. This increase was not found in idiots. The plaques were in no sense necrotic; he asked how they stained with aniline dyes. Pick's disease was often overlooked, being taken for part of the cortical atrophy of old age: the disease was not necessarily limited to the frontal region, and might be related to genetically recent parts of the brain. Subcortical encephalitis had not been mentioned.

Dr. J. H. Earls asked whether the plaques which arose away from blood-vessels had anything to do with lack of blood-supply, and were comparable to similar changes in the myocardium.

Dr. Percy Smith spoke of the correlation of the new pathological findings with clinical observations. Some patients, who might be expected to have senile dementia, recovered, even at an advanced age.

Dr. C. W. Brasher asked if these atrophic changes were in any way associated with valvular disease of the heart. Cardiac cases were apt to become hallucinated during the night.

Dr. G. W. James said that Alzheimer's disease did not really belong to the senile psychoses; presbyophrenia and senile dementia were the outstanding examples, and were nearly always associated with increase of pressure and of cholesterol in the cerebrospinal fluid. The latter provided a prognostic point, for if it was low there was some hope of recovery.

Dr. Critchley, in reply, said he thought that theoretically senile changes and cerebral arteriosclerosis were entirely separate, although they were often coexistent. Subcortical encephalitis was essentially an arterial change. Changes in the choroid plexus were early and marked, and metabolic changes and increased permeability both played an important part in cerebral senility. Toxins which normally could not reach the cerebro-spinal fluid might in these brains be able to get through. Plaques stained only faintly with aniline dyes and required silver stains. The occipital cortex was commonly but the motor cortex very rarely affected in Pick's disease. The cardiac cases were probably associated with an ischæmic condition of the brain.

Purchase of St. Bartholomew's Close.—The governors of St. Bartholomew's Hospital have acquired St. Bartholomew's Close which is at present built over with shops, offices, and warehouses. It is hoped eventually to clear the site and erect upon it a residential college for students when means permit.

NORTH OF ENGLAND OBSTETRICAL AND GYNÆCOLOGICAL SOCIETY.

At a meeting of this Society held at Manchester on Dec. 15th **Dr. Gordon Fitzgerald** gave a presidential address in which he pleaded for moderation in the "much too prevalent abuse of the trust placed by patient in doctor." He drew attention to the deplorable frequency with which details of illnesses and operations were divulged—the patients being referred to by name and discussed under conditions which left no doubt that the medical attendant was violating the confidence placed in him. He also pleaded for moderation in the extent to which the material advantages were permitted to dominate medical opinions of patients' ailments. Those practising gynæcology must be particularly on their guard against this, he said, for the general ignorance of the pelvic organs made people especially gullible on this subject.

Prof. Daniel Dougal demonstrated radiograms of

An Anencephalic Fœtus.

The patient was a primigravida aged 33, who was apparently three weeks post-mature. The fœtus lay transversely. The breech was distinctly felt to the right but the head was not satisfactorily defined. External version was attempted under anæsthesia but failed. An X ray photograph was taken and the radiologist reported that the cranial vault was not developed, and that there appeared to be defects of the lower cervical and upper thoracic spine. Medicinal induction was commenced, and an anencephalic fœtus was delivered normally 18 hours later.

Dr. Archibald Donald said he had recently seen a case in labour with some antepartum hæmorrhage where he could not feel a head. The patient's doctor wanted him to perform a Cæsarean section. He refused, and an anencephalic fœtus was shortly afterwards delivered.—**Mr. Leyland Robinson** showed a radiogram of an anencephalic fœtus for which previously he had considered treatment by Cæsarean section.—**Dr. J. W. Burns** referred to his "flying fœtus," already reported to the Society, which was diagnosed by X rays.

Dr. W. W. King reported a case of

Injury to the Rectum

caused by administration of a simple enema after labour. He referred to a case recorded by Prof. Fletcher Shaw in 1922, which resulted in permanent occlusion of the rectum.

In Dr. King's case a simple enema was given to a 6-para three days after a perfectly normal parturition. There was pain during the injection, with some bleeding and immediate swelling of the perineum. On the next day the pain spread to the abdomen, and she vomited. Twenty-four hours afterwards her condition was serious, with signs of peritonitis, and the perineum was enormously swollen and œdematous. The abdomen was opened, and purulent fluid (subsequently found to be sterile) was evacuated. The rectum and sigmoid were greatly swollen and dark blue in colour. A colostomy was performed, the peritoneal cavity drained, and a free incision was made into the perineal swelling.

Convalescence, said Dr. King, was stormy, and a stricture of the rectum resulted about 2½ in. above the anus. Five months later the colostomy was closed, but the stricture still remained, necessitating the regular use of rectal dilators. The hard nozzle of the enema syringe had been inserted into the rectum, and a sample of the soap used showed that it contained more free caustic and carbonate alkali than the British Pharmacopœia standard. He concluded that a soft catheter only should be inserted into the rectum.

Prof. Fletcher Shaw referred to his case, in which the injury had been caused during labour, and he had not seen it until three months later.—**Miss Ruth Nicholson** had seen two cases, in one of which the injury had occurred just before delivery and the other some time before the completion of labour. In the latter forceps were used to complete the delivery, which was followed by sloughing of the rectum and vaginal walls, and the prolapse of gangrenous loops of tissue out of the cavity, much resembling coils of small gut. This was followed by the death of the patient. Mr. KELLY had seen a similar case which he believed to be due to sloughing of the rectal mucous membrane, the enema fluid having been too hot when injected.

Prof. FLETCHER SHAW described a case of

Acute Sacculation of the Uterus.

This patient was a primigravida, 31 years old, and about three months pregnant. After two days' severe abdominal pain a cystic tender swelling was discovered on the upper surface of the uterus and of about the same size as the uterus. The swelling proved to be a thin-walled sac of uterine wall, and its cavity communicated with the cavity of the uterus by an opening which admitted two fingers. Both the sac and the uterine cavity were lined by fœtal membranes, and the fœtus moved freely from one to the other. The placenta was within the uterine cavity.

Two years later, said Prof. Shaw, the abdomen was again opened, and a slight groove could then be detected running across the fundus down both the anterior and posterior walls of the uterus which gave rise to the suspicion that there was some weakness at the place of fusion of the two Müllerian ducts, and that this place was unable to withstand the extra pressure due to the growing ovum, and so stretched to form this thin-walled sac.

Dr. J. W. BRIDE had seen a similar case in a primipara, but the whole uterus was involved.—Dr. DONALD had seen an infantile uterus becoming pregnant; the wall was very thin, but the patient had a normal labour.—Mr. J. ST GEORGE WILSON (Liverpool) suggested that the case was one of incomplete rupture of the body of the uterus.—Dr. S. B. HERD (Liverpool) suggested that there was malunion between the two halves of the uterus.

Prof. DOUGAL read notes of a case of

Hydradenoma of the Vulva.

The patient was a single woman, aged 52. There was a small cauliflower excrescence on the vulva about half an inch in diameter, pinkish in colour and situated on the left labium minus, a short distance below its bifurcation. The growth was removed locally and examined microscopically. The vulva was excised four weeks later. Prof. Shaw Dunn reported that the growth was an adenoma hydradenoide.

In these tumours, said Prof. Dougal, the growth resembled a small cauliflower projecting outwards beneath the epithelium. It was covered by stratified squamous epithelium which in some places was much thickened and in others worn away by friction. Leading down from the surface epithelium were several duct-like tubes which could be seen to merge with the mass of tubules of which the main tumour proper was composed. The tubules formed a complicated system, but were of uniform appearance, being lined by two layers of cells, an inner cylindrical and an outer cuboidal. In places there were masses of cells strongly suggestive of malignancy. The tubules resembled the ducts of sweat glands, and the tumour had evidently originated in one of these structures. The literature showed the difficulty of deciding whether these tumours were malignant. Outerbridge and Schwartz regarded as malignant any tumours of this type in which the acini had invaded the stroma or in which masses of polyhedral cells were found in the same situation. He had done a radical operation in this case because of the masses of polyhedral cells seen in his sections.

Sections showed the tumour to be a rapidly growing fibrosarcoma.

Prof. DOUGAL also reported a case of

Malignant Body of Uterus Incarcerated in a Procidentia.

The patient was a single woman, aged 58, and five years past the menopause. She had had prolapse for five years, and for the last four years it had been complete. Her main complaint was severe pain in the lower abdomen and in the procident mass; this was evidently due to incarceration of the contents, for the prolapse could not be reduced. There had been some irregular hæmorrhage for two weeks. Vaginal hysterectomy with colporrhaphies was performed. The uterus contained a large necrotic growth which proved on section to be an endothelioma. The right ovary contained a nodule of similar growth.

The points in this case were: (1) the occurrence of complete prolapse in a nulliparous woman; (2) incarceration of the enlarged uterus in the procidentia; and (3) the nature of the tumour—an endothelioma.

Mr. N. L. EDWARDS (Derby) showed a specimen of primary squamous-celled carcinoma of the vagina, and Prof. DOUGAL demonstrated radiograms from a case of intestinal carcinoma, and described a case of sarcoma of the broad ligament.

AUSTRALASIAN COLLEGE OF SURGEONS.

ANNUAL STATE MEETING IN QUEENSLAND.

AT the meeting of the College held in Brisbane on Nov. 15th, 1929, an address was given by Dr. R. B. WADE, of Sydney, on

LEFT LUMBAR RAMISECTION IN HIRSCHSPRUNG'S DISEASE.

The condition, said Dr. Wade, was described first by Parry in 1825. Of the many theories advanced to explain the causation that of neuromuscular incoördination was most widely accepted. There was the double innervation of the bowel to bear in mind, and the various sphincters, particularly that described by O'Beirne at the pelvirectal junction. Two theories of the action of the sympathetic were held: (1) that it was the active agent in causing contraction of the sphincters, (2) that its function was to maintain postural tone (Hunter and Royle). In this way the viscera adapted themselves to changes in volume of their contents, and the sphincters contracted until the call came for the passage of the contents. On the one theory there was active contraction, on the other an absence of relaxation; in either case overaction of the sympathetic would give the same result. With the former view hypertrophy of the sphincter would be anticipated.

In the development of the child, Dr. Wade went on, the inhibitory apparatus lagged behind the motor and was last acquired. In infantile achalasias, such as those at the cardia and pylorus, the time limits of the obstruction appeared definite, and if the child survived until the time that inhibition was acquired it would recover. This did not appear to apply to achalasias of the rectum. The achalasias appeared at different periods; they might occur in the very early days of life as a result of incoördination, or in later life, owing to a local degeneration of the neuromuscular mechanism. Hurst considered the disease to be due probably to an incoördination resulting in failure of relaxation at either the pelvirectal sphincter or the internal sphincter ani. In Hirschsprung's disease there was no proof of hypertrophy of either of these sphincters, and clinically there was no spasm. Dr. Wade, however, quoted three examples which suggested some form of obstruction occurring at the pelvirectal sphincter in these patients.

The three cardinal symptoms and signs were constipation, abdominal distension, and peristaltic waves; of these the latter might be absent in the milder cases. Constipation was the predominant symptom. Attacks of abdominal distension occurred, associated with vomiting; these usually were relieved by freely emptying the pelvic colon. X rays showed the bowel evenly distended with a smooth contour and an absence of haustration. Administration of insufficient enema might cause fallacies; a baby suffering from Hirschsprung's disease could retain 1½ pints, an older child 2 pints. In treatment, diet alone had not been a great success; a daily purge and enema would keep the child in moderately good health; dilatation was stated to have had some success. In ileosigmoidostomy and colectomy the anastomosis must be made above the sphincter; following it the dilatation reproduced itself in the ileum.

A Series of Cases Described.

Operation on the sympathetic, as suggested by Dr. N. D. Royle, had been carried out in 13 patients, with, in the main, satisfactory results. In this operation, an exposure of the left lumbar trunk of the sympathetic was made through a lumbar incision, somewhat similar to that exposing this part of the ureter. The nerves severed were the white ramus from the first lumbar nerve to the first lumbar ganglion and, if there was a large branch from the second nerve to the second ganglion, this also was divided. All the branches (usually four) leaving the ganglion on the medial side, and one from the first and second ganglia, and one or two smaller ones from the fourth were severed, and the cord cut across below the fourth ganglion. Operation on the left side only was found to be sufficient in all the patients except one. Dr. Royle had shown in experiments on goats that when this operation is carried out on both sides, though no actual paralysis of the sphincters occurs, micturition and defæcation become more frequent.

Thirteen patients were submitted to operation, their ages ranging from one month to 12 years. There was one death, that of a child, who died from pneumonia two months after operation. One child showed no improvement until the operation had been performed also on the right side. The remaining children showed considerable improvement in their general condition and constipation was relieved, while the abdominal distension and dilatation of the colon remained unchanged. There was, however, a gradual decrease in the size of the abdomen and in the calibre of the distended colon. In the first patient, operated on in August, 1926, the abdomen was now almost flat, although a distended pelvic colon was palpable; X rays taken some years after the operation showed haustration in the ascending colon. The operation relieved the constipation completely. The improvement manifested itself soon, but not necessarily immediately, after the operation. Care must be taken to ensure regular habits.

Dr. Wade also described the case of a girl aged 19, suffering from visceroptosis with marked constipation, in which the operation was carried out. The excellent result obtained suggested that this was a somewhat similar condition of neuromuscular defect.

SHEFFIELD HOSPITAL FINANCE.—The budget for 1930 of the Sheffield Joint Hospitals Council estimates the expenditure of the four voluntary hospitals of the city at £169,035; the expenditure of the council services is put at £28,000. The ordinary income of the four hospitals, apart from receipts from the penny-in-the-pound scheme, is estimated at £42,381, and the amount to be raised by the Joint Hospitals Council at £145,744.

WORKSOP POOR-LAW INFIRMARY.—Mr. Arthur Neal, chairman of the Sheffield Board of Guardians, last week opened extensions of this infirmary at Kilton Hill. The enlargements include a new administrative block and nurses' home, and rooms for the medical and nursing staff. Mr. Neal pointed out that, when the work of the guardians is taken over by the county council, it will be necessary to extend existing institutions or build new ones if waiting-lists were to be done away with.

ST. MARY'S HOSPITAL, PORTSMOUTH.—Dr. R. C. Macpherson, the medical superintendent of this hospital, states that the record of its nurses in the State examinations "has never been beaten by any institution in the country." They held a record of 100 per cent. successes for two years and nearly 100 in the other three years. "Only on one occasion, and that for one year only, has any other institution gained 100 per cent. success in that examination." The hospital contains 1000 beds and the daily average of patients is 950. It is not a surgical hospital, but last year there were 800 operations.

Reviews and Notices of Books.

PUBLIC HEALTH AND HYGIENE.

Public Health and Hygiene in Contributions by Eminent Authorities. Second edition. Edited by WILLIAM HALLOCK PARK, M.D., Professor of Bacteriology and Hygiene, University and Bellevue Hospital Medical College, and Director of the Bureau of Laboratories of the Department of Health, New York City. Philadelphia: Lea and Febiger. Pp. 902. $9.

THE second edition of this book, which has been thoroughly revised and brought up to date, is a welcome addition to the rapidly growing literature of preventive medicine. It is divided into 34 chapters contributed by 24 well-known writers, each dealing comprehensively with his own particular specialty. The work is really a series of authoritative monographs so planned that while each is in itself a complete résumé overlapping and repetition are avoided and the finished product is a homogeneous and concrete whole. The treatment of public health problems is, of course, essentially American, but there are many references to English and continental standards and practice.

Almost one hundred pages are devoted to bacteriology and immunology as applied to public health, including a full description of modern methods of diphtheria prophylaxis—a subject of which Prof. Park writes with the authority of a pioneer. The claim that this procedure confers life-long immunity against diphtheria, however, must be regarded as premature; the statement that sewer gas predisposes to this disease seems out of place in a work containing so much sound, modern teaching. We doubt whether the recommendations of the American Public Health Association for the community control of influenza (pp. 98–103) deserve the space accorded them in a work of this kind. Again, the absolute isolation of public institutions for the whole of an influenza epidemic, and for some weeks before and after, is a counsel of perfection which under modern conditions hardly permits of practical application. In view of the reports from Canada as to its value it is surprising to find no reference to the serum treatment of anterior poliomyelitis (p. 117). The emphatic statement that vaccination is the only satisfactory means of controlling small-pox requires some modification in the light of modern experience of the non-classical type of the disease, about which nothing is said, and the assertion that there are no contra-indications to vaccination takes no consideration of work on post-vaccinal encephalitis. Not many of our cities can have been so fortunate as New York, where (p. 144) "there has not been a death for several years from any complications of vaccination." It is disappointing to find the consideration of the differential diagnosis of small-pox compressed into a rather unhelpful footnote. A separate chapter is given to aseptic technique in the handling of communicable diseases; the busy medical superintendent of a large fever hospital in this country is likely to reject the scheme outlined as impracticable, by reason of the time involved in its execution and difficulties of staffing. The section on epidemiology (pp. 248–259) is eminently practical and concludes with a recital of some of the unsolved problems in the transmission of communicable diseases, together with a plea for combined effort in their elucidation. The subject of ventilation is thoroughly dealt with; the British reader will be astonished to learn that the Americans were first in the field with the modern conception that physical rather than chemical factors are responsible for the vitiation of the atmosphere.

The present state of our knowledge of vitamins is described in a useful section in which irradiated milk is strongly advocated as a potent agent in the prophylaxis of rickets. The American preference fod cleaned rather than clean milk appears again anr again. One wonders what were the *B. coli* contents of the samples in which total bacterial counts were measured in millions per c.cm. In their regulations for controlling milk-supplies the Public Health Council of New York State include the power to examine body discharges of workers in pasteurised and general milk-supplies. A useful note is that on oyster contamination viewed from the bacteriological aspect. The figure for the incidence of defective vision among school-children, suggested by the American Council of Eyesight Conservation (60 per cent. so defective as to need correction), astonishes us, and that for juvenile mental deficiency (2 per cent. of the population) is also surprisingly high. The procedure described for the school exclusion of infectious diseases contacts seems unnecessarily cumbersome; the treatment of ringworm of the scalp recommended (p. 691) is much less effective than X ray therapy. Useful sections are those dealing with social and economic factors in relation to disease transmission and infant mortality. Those on mental hygiene and maritime hygiene are also good; in the latter the amount of sulphur necessary for effective ship fumigation is, however, overstated and no reference is made to the International Convention of Paris, 1926. The value of mental hygiene in relation to the child guidance movement and the prevention of juvenile delinquency is clearly stated, and the rôle of the nursery school as a promoter of mental hygiene is convincingly explained.

We have indicated places where it seems that further attention might well be employed in the improvement of the book, but the suggestions for emendation are few when its scope is considered, while of its value for reference there can be no doubt.

STARLING'S PRINCIPLES OF HUMAN PHYSIOLOGY.

Fifth edition. Edited and revised by C. LOVATT EVANS, D.Sc., F.R.C.P., F.R.S., Jodrell Professor of Physiology in University College, London. The chapters on the Central Nervous System and Sense Organs revised by H. HARTRIDGE, M.A., M.D., Sc.D., F.R.S., Professor of Physiology at St. Bartholomew's Medical College. London: J. and A. Churchill. 1930. Pp. 1039. 21s.

IT is satisfactory to find that this well-known book, which has assisted generations of students through the higher examinations in medicine and physiology, is not to pass away with its original author. Prof. Lovatt Evans states in his preface to the fifth edition that Prof. Starling asked him to revise the work immediately after the war, but that he was unable to do so then. After Starling's death, however, he felt compelled to accept a task which it was clearly his colleague's wish that he should undertake. It is not necessary at this stage to describe the contents, aims, and objects of this work. One who wishes to obtain a sound knowledge of physiology can do no better than read it carefully and to make it the foundation of his knowledge. This applies equally to men working for their medical examination or for more advanced ones, such as the primary fellowship or the higher examinations in medicine. If students read this book thoroughly and carefully before proceeding to speculative and possibly transient monographs, the examiners for higher degrees would not so frequently encounter candidates whose general physiological knowledge is sadly defective.

The most notable addition to the book is the complete revision of the chapters dealing with special senses and the central nervous system by Prof. H. Hartridge. The last-named section contains a whole series of chapters or parts of chapters on postural reflexes, group control, and conditioned reflexes. The section on the physiology of muscle and nerve reflects the teaching of Prof. A. V. Hill and his co-workers, and in itself provides an almost complete monograph. The subject of oxidation and reduction in the animal body seems unduly compressed. In hardly more than two pages Prof. Lovatt Evans has certainly summarised the new work admirably, but no mention has been made of the oxidation reduction potential theories, and reference to the work of Otto Warburg might well have been expanded; only some two or three lines are devoted to this important work on tissue respiration and glycolysis—indeed very little is said about glycolysis anywhere in the book. The section dealing with gastric secretion is rather involved. The methods for investigating normal human stomachs are not described until comparatively late in the chapter, when the fractional method of gastric analysis is dealt with. In his desire to include all the latest work on the subject Prof. Lovatt Evans has included observations which contradict each other. The section on metabolism has been altered considerably, and the most recent views on insulin have been included. Perhaps the greatest changes involve the section on reproduction. This section now includes much recent work on the ovarian and œstrus-producing hormones; the relationship between the secretion of the anterior lobe of the pituitary and ovarian function is not discussed.

The work as a whole commands whole-hearted admiration; it will undoubtedly remain one of the most popular standard text-books on physiology in our language.

PULMONARY TUBERCULOSIS.

La tuberculose pulmonaire: guide du malade et du prédisposé. By Dr. JACQUES STEPHANI, Montana. Paris: Payot. Pp. 314. Fr.25.

IN 1928 Dr. Stephani wrote a small book in English entitled "Consumptive," to which this is complementary. Both books are written in large measure for the guidance and instruction not only of the medical man, but of the patient. It is addressed to a class of patients, differing markedly in their psychology from any other class. The amazing optimism, the cheerfulness of the young person suddenly deprived of liberty, the alternating phases of exaltation and depression, are familiar to all those who have to do with the tuberculous patient, and cannot be lightly dismissed. The fact that many of these patients study any medical book dealing with their condition, often to their mental distress, makes us view with sympathy a book such as this one, written in an encouraging style by a physician who is possessed of genuine knowledge of his subject. It can do no patient harm to read the heading to Chapter XIV., "Pulmonary Tuberculosis is the Most Curable of all Chronic Diseases," and he will be greatly helped in his fight by a study of the delightful Japanese fable at the introduction to Chapter XXIV., in which the author deals with the grave question of the personal responsibility of the patient. The book is written in simple and not over-technical language. It omits nothing of importance, and may be read with profit by all whose daily work brings them in contact with that most delightful, though possibly difficult patient—the individual who has been notified as suffering from pulmonary tuberculosis. Such a patient may at first be apt to regard himself as isolated from the rest of humanity. His reactions to the realisation of the fact that his mode of life and his activities have been profoundly altered, and that the change must last for a long period of time, will be favourably influenced by the study of this book.

La pratique du pneumothorax et de la collapsothérapie chirurgicale. By F. DUMAREST and P. BRETTE. Paris: Masson et Cie. 1929. Pp. 409. Fr.50.

THIS is a very complete account of the treatment of pulmonary disease by collapsing the lung. The first nine chapters deal with artificial pneumothorax. Many different types of apparatus used for this purpose are described, some very simple and others complicated, but all effective, so that the choice of apparatus really becomes a matter of individual preference. The authors point out that a pneumothorax depends on the elasticity of the lungs and on the respiratory muscles, and that it is not merely a matter of compressing the lung by so much pressure of air. The collapse depends upon the individual. The immediate and late results of pneumothorax treatment are given, and there is a good discussion of the vexed question of when the lung should be allowed to re-expand. A chapter is devoted to bilateral pneumothorax, and the effects of collapsing both lungs simultaneously are compared with those of collapsing first one lung and then the other. The last chapter deals with phrenicotomy and thoracoplasty, and the indications and advantages of these surgical methods are compared with those of artificial pneumothorax. The book is very readable, and has a full list of references.

ULTRA-VIOLET RAYS.

Ultra-violet Rays in the Treatment and Cure of Disease. Fourth edition. By PERCY HALL, M.R.C.S., L.R.C.P., Hon. Actino-Therapist, Mount Vernon Hospital. London: William Heinemann, Ltd. 1929. Pp. 248. 12*s.* 6*d.*

THE fourth English edition of this manual—there have also been two American editions—has been brought up to date and contains some new features. Two new chapters, one on self-administration and one on dosage, will prove of value to the beginner. The information given in this popular introduction to actinotherapy is clear and accurate, although elementary in its presentation. There is a laudable attempt to avoid speaking of "ray-therapy" as a whole, and the author is at pains to point out that waves of different wave-lengths may initiate very different if not opposing reactions. Dr. Percy Hall is an enthusiastic believer in actinotherapy for selected cases of pulmonary tuberculosis. Unlike most other workers in this field he makes extensive use of the tungsten-arc lamp and in cases of laryngeal tuberculosis directs both the light and the fumes of this lamp into the air passages. In his introduction to this manual Sir Henry Gauvain states that he has used Dr. Percy Hall's tungsten-arc lamp with excellent effect, and that the good results obtained by the author will induce others to follow in his footsteps.

EMBRYOLOGY AND ANATOMY.

The Essentials of Human Embryology. By GIDEON S. DODDS, Ph.D., Professor of Histology and Embryology, School of Medicine, West Virginia University. New York: John Wiley and Sons. 1929. Pp. 316. 20*s.*

FOR some years past a steady flow of books on embryology has set in from across the Atlantic, any one of which might, in many ways, serve in place of one of the others if this were by mischance mislaid. Most of them give the reader beautiful figures showing the gymnastic contortions of chromosomes, other beautiful figures with which we have been on intimate terms since the earliest days, and still more beautiful figures of sections of chicks or pigs or other interesting but non-human embryos. They provide as a rule good accounts of the early conditions and general questions connected with development, and then furnish quite inadequate and sometimes misleading descriptions of organogenetic processes. There seems to be a desire to cut down details of the actual formative occurrences in the various parts of the body to a minimum. Surely this is not the right way to make the development of the body of value; it would seem that the standard adopted was set by an examination syllabus rather than by a wish to give some understanding of the subject to the reader. One knows what one will find before opening one of these works. They all grind out the same melody, only altering the key. Presumably they are absorbed, since they are produced, but anyone fortunate enough to possess one of them might refrain from spending money on its successors, at any rate for a few years. Moreover, we cannot help feeling that organogenetic development, as it is taught in England to-day, is more consonant with the facts and of more use and value than some of the hoary legends which serve their turns beyond their normal span of life.

Dr. Gideon Dodds's book is in many ways free from these faults. The figures are good and are mostly new and selected for their object. The text is pleasantly written, in good English. The general accounts are clear and adequate, but we would have liked to see more topographical detail in the descriptions of development of organs and regions. It is possible that this may be due to the effort to meet the word "Essentials"; anatomical "essentials" for the neurologist differ from those considered essential by the gynæcologist, and similar relativities hold in the world of descriptive embryology. In any case Gideon Dodds has produced a very readable book, even if the multiplication of the species to which it belongs calls for mild protest.

Applied Anatomy. Eighth edition. By GWILYM G. DAVIS, M.D., late Professor of Orthopædic Surgery and Associate Professor of Applied Anatomy, University of Pennsylvania. Revised by GEORGE P. MULLER, M.D., Professor of Clinical Surgery in the University. London: J. B. Lippincott Company. 1929. Pp. 638. 42*s.*

THIS well-known work, which has been brought out three times since Prof. Davis's lamented death, is now issued again with some slight revision. It is unnecessary to do more than call the attention of readers to this fact, for the book has long passed the stage of criticism and is one of the standard medical works.

RACIAL HYGIENE.

Die Deutschen und ihre Nachbarvölker. Neue Grundlegung der Anthropologie, Rassen-, Völker-, Stammeskunde und Konstitutionslehre nebst Ausführungen zur deutschen Rassenhygiene. By Prof. Dr. WALTHER KRUSE. Leipzig: Georg Thieme. 1929. Pp. xiv. + 640. G.M.41.

Prof. Kruse is Director of the Institute of Hygiene of Leipzig University, but in this book he is concerned almost entirely with anthropological and not medical matters. His interest in both subjects dates from more than 40 years ago, when he worked for a time with Rudolf Virchow.

Abrupt opening is made with a criticism of the scales used to match hair and eye colours, and the presentation of new ones which are said to be comparable with the widely used scales of Fischer and Martin. The most important statistics which have been compiled for integumentary colours are then considered. As with the other body characters, the distribution within Germany is first dealt with and then the distribution for Europe as a whole. The frequencies are represented on good maps. Other features discussed in turn are the stature, cephalic index, and several facial measurements, and reference is also made to the available material relating to skulls. The nature of the profile is then considered in detail, as it can be appreciated from living and cranial measurements and qualitative descriptions, such as the grouping of nose-shapes. Composite photographs of the full face and profile views of 28 groups of German men, and of all the groups combined, comprising 800 individuals, are given in Plates III. and IV. and there are some composites for other races in Plate V. These have evidently been prepared with great care, but they are unfortunately reproduced on a very small scale. Body measurements and the blood tests used in recent years, which are claimed to discriminate racial types, are also dealt with.

After treating the living populations thus Prof. Kruse discusses the relationships of extinct races as they are known from a study of their skeletons and principally of their crania. Nearly half of this long book is taken up with the presentation of data such as these, the characters being considered separately and with regard to their geographical distributions. The remainder is concerned with an attempt to reconcile the conclusions which the different kinds of evidence suggest and with the more general aspects of the subject, such as the variability and correlation of the characters, the way in which they are inherited, and the effects of environment and selection. The association of the various anthropological characters is considered in detail. This is the weakest part of the book, since the author, though acknowledging the need for metrical description, has refused to use modern statistical methods and his treatment by percentages is out of date. The relations of race, mentality, and culture are also dealt with. In conclusion, the presumed racial constitution of German peoples is set forth and something is said of their racial hygiene.

This book may be recommended to anyone who is interested in the main results of the anthropological investigations into the constitution of European races in general, and of the races of Germany in particular, which have been conducted in the past 50 years. It is a conscientious summary of a vast mass of material.

ESSENTIALS OF MEDICAL ELECTRICITY.

Sixth edition. By ELKIN P. CUMBERBATCH, B.M. Oxon., D.M.R.E. Camb., M.R.C.P., Medical Officer in Charge, Electrical Department, St. Bartholomew's Hospital. London: Henry Kimpton. 1929. Pp. 443. 10*s.* 6*d.*

SINCE the publication of the last edition of this well-known text-book eight years ago several important developments have taken place in the art of electrotherapeutics. One of the chief of these is the extension of the use of diathermy, especially in the treatment of disease of the pelvic and genital organs. Dr. Cumberbatch has accordingly entirely rewritten his chapter on diathermy, and has incorporated the methods devised by his colleague Dr. C. A. Robinson. He has also surveyed the uses of diathermy and high-frequency currents in surgery. The revision, as the result of experience, of our early ideas about ionisation has led to an unfortunate neglect of galvanotherapy in general. The author has, however, stressed the value of the direct current apart from its "iontophoretic" properties, which are now recognised to be very limited, and has amplified the sections on iontophoresis without therapeutic ions—or ordinary direct current treatment—and on electro-chemical cauterisation, the other two branches of galvanotherapy. New chapters on the sinusoidal current, and the combination of acupuncture with the galvanic current, have been added. The difficult subject of electrical reactions has been elucidated by several new diagrams; the use of condensers is described, and a section has been inserted on the difficult concepts of chronaxie and rheobase. The whole volume has received detailed revision, and can be commended anew as a thoroughly comprehensive and up-to-date work.

VERNES TEST IN TUBERCULOSIS.

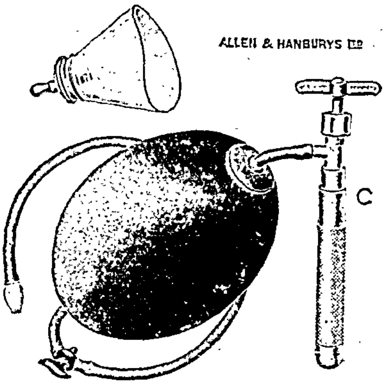
Étude de la réaction de Vernes a la résorcine dans le diagnostic et le pronostic des tuberculoses. By ANDRÉ BRETON, Ancien Interne des Hôpitaux de Lille; Preparateur a l'Institut Pasteur. Paris: Masson et Cie. Pp. 150. Fr.20.

THIS book is a monograph dealing with the application of the Vernes flocculation test for syphilis to the field of tuberculosis. The test consists in the estimation of the amount of flocculation produced when resorcin is added to the serum of a tuberculous patient. This estimation is carried out by means of a Vernes photometer, introduced by the worker whose name it bears, and used extensively in the Institut Prophylactique in Paris. Vernes divides the readings into three zones: (1) negative; (2) intermediate or doubtful; and (3) diagnostically positive. The claim is made that, with the accurate technique of the elaborately constructed photometer, better results can be obtained than with other diagnostic serum tests. This monograph assembles results obtained by various workers, with some case-records, curves, and a bibliography. The complement-fixation test for tuberculosis is also touched upon, but merely to make an unfavourable comparison of its value with that of the Vernes test. No description of the Vernes apparatus is given in the book. In our view the specificity of flocculation with resorcin and tuberculous serum is still unproven, and in any case, the cost of the Vernes apparatus puts it outside the scope of most clinical laboratories. This monograph seems to be an attempt to vindicate the results obtained by the advocates of the test, rather than a working description of the technique, or a critical analysis of the methods.

Corrigendum.—The author of a Manual for Patients Suffering from Diabetes Mellitus, reviewed on p. 84 of our last issue, is Dr. J. Knowles Lund. We regret the inaccuracy.

New Inventions.

PORTABLE OXYGEN INHALING APPARATUS.

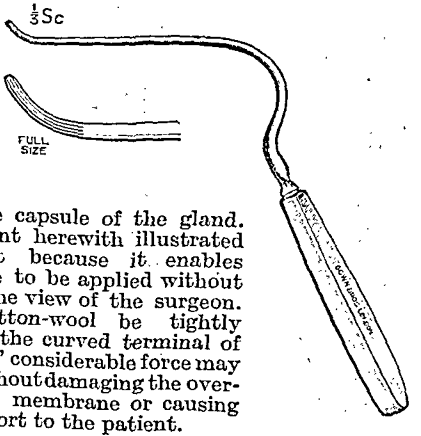


PATIENTS who find relief from oxygen inhalations have complained of the inconvenience of the large oxygen cylinder when they are travelling. In order to meet with this difficulty, Messrs. Allen and Hanburys, Ltd., Wigmore-street, London, W., have made for me a small portable apparatus which is illustrated above.

London, W. L. S. T. BURRELL, M.D.

A TONSIL PRESSOR.

IT is a common experience to find that a healthy looking tonsil contains septic material in the depths of its crypts and that this can only be made to exude on the surface of the tonsil by pressure on the outer and embedded regions of the capsule of the gland. The instrument herewith illustrated is convenient because it enables such pressure to be applied without obstructing the view of the surgeon. If some cotton-wool be tightly wound round the curved terminal of the "Pressor" considerable force may be exerted without damaging the overlying mucous membrane or causing much discomfort to the patient.



The instrument has been made for me by Messrs. Down Bros., St. Thomas's-street, S.E.

HERBERT TILLEY, F.R.C.S.

THE LANCET.

LONDON: SATURDAY, JANUARY 18, 1930.

CHEST COMPLICATIONS AFTER OPERATION.

DURING the last few years the problem of postoperative pulmonary complications has been approached from many different angles. A great deal of experimental work has been done, and although its results are much what might have been expected, they nevertheless serve to emphasise facts which are apparently obvious and correspondingly often overlooked. For instance, it is hardly surprising to find that a patient's vital capacity is considerably reduced by having a large and recent incision in the abdomen and his lower ribs constricted by a tight binder, but it is important to realise how great this reduction may be, and after which operations it is greatest. Again, few would question the possibility of producing pneumonia by introducing virulent organisms directly into the lungs, yet some observers who realise how difficult it may be to infect dogs in this way would prefer to regard postoperative pulmonary infections as being conveyed to the lungs from the site of operation by way of the blood or lymph stream. The painstaking researches of CHARLTON BRISCOE and others have shown that the physiology of respiration and the normal function of, and balance between, the various respiratory muscles is not so simple as it once seemed.

In spite of all this work it is clear that no great advance has been made in reducing the frequency of these complications, for in our present issue Dr. C. J. FULLER records a series of cases with a higher incidence of complications than any similar series of recent years. His analysis, like others, shows that pulmonary complications most frequently follow operations on the mouth, larynx and pharynx, and those involving an abdominal incision. Other important factors, in his opinion, are preoperative infections of the lung, and toxic complications such as perforation of an ulcer or strangulation of a hernia. The complications fall naturally into two groups—the embolic and the inflammatory. As regards the inflammatory group, it is pretty generally agreed that either a chronic infection is stirred into activity by the anæsthetic or that septic material is inhaled into the lungs during unconsciousness; and it seems reasonable to make inhalation responsible for the prevalence of pneumonia after operations on the mouth and throat. All the same, some observers hold that there is really only one group, and that postoperative pneumonia is caused by irritation or infection of the lungs by a shower of minute emboli arising from the site of operation. FULLER sides with the majority in rejecting this theory. The main arguments against it are, first, that in a very large number of cases no site of origin for the supposed emboli has been found post mortem; secondly, that cases of undoubted infarction run a different clinical course from the majority of postoperative pneumonias and have characteristic features at necropsy; and, thirdly, that it does not account for the prevalence of chest complications in two definite groups of operations and their comparative rarity in others. However distinct the two groups may be in their pathology, there is a growing weight of evidence that they have an important common factor—namely, inertia, and particularly diaphragmatic inertia. Inhibition of the diaphragm by the pain of stretching an abdominal incision, and of the lower ribs by a tight binder, will clearly reduce aeration at the bases of the lungs. If a portion of lung is airless, the secretion cannot be coughed out of it, for the action of a cough is that of a pop-gun, and without air behind it the sputum, like the cork, will remain stationary. It is for this reason that in many case of bronchiectasis posture is the only means of draining away the sputum; it lies at a dead end with no air behind it. If septic material has been inhaled during the unconscious period it will tend to stagnate in the lungs as a whole, because the range of respiratory movement in a patient lying quiet and prostrate in bed will be small; it will be especially small at the bases because, for the reasons given, aeration in this region is specially restricted. Further, the strength of a cough depends on the vigour of contraction of the abdominal muscles, and if these are the site of a more or less painful incision they are not likely to contract briskly; so, even if air is present, coughing will be painful and therefore weak. Inhibition of these muscles also has another effect. The venous circulation from abdomen to thorax is very largely maintained by the production of a negative pressure in the chest, and a simultaneous rise of pressure in the abdomen, by means of diaphragmatic contraction during inspiration. It has been suggested that this mechanism is impaired after abdominal operations, the result being venous stasis and a liability to thrombosis and embolism. In practice two questions have to be answered: how can we best avoid introducing septic material into the lung, or lighting up a latent infection, and how can we best maintain efficient pulmonary ventilation, and particularly diaphragmatic movement, after the operation is over? Attempts to answer the first of these questions include administration of atropin before anæsthesia; routine dental and pulmonary examination before operation; adoption of a special posture or plugging of the fauces in operations on the mouth; and either modification of the standard anæsthetic or postponement of the operation if chronic infection is found. When we come to the second question it must be admitted that few systematic attempts to deal with the problem have been described. It is of interest that FULLER reports the result of an experiment in organised deep breathing, and while it is to be feared that his popularity in the wards was not enhanced, and the result was discouraging for the reasons that he indicates, there can be no doubt that theoretically such respiratory gymnastics are absolutely correct. If abdominal cases (whenever possible) were nursed in Fowler's position, directly they had recovered from the anæsthetic, and made to recline first on one side and then on the other, so that each lung in turn was put in the best position for full expansion, better results might perhaps be obtained. The relatively small incidence of pulmonary complications in lower abdominal cases may be due to their being often nursed in Fowler's position.

There is a third type of pulmonary complication which may follow operation—namely, massive collapse. Here, again, there are two schools of thought, which seem to depend to some extent on whether the observer has been studying postoperative cases or not. Many cases have been reported, particularly during the late war, in which massive collapse followed rapidly on an injury to the abdomen or chest. Some of these injuries were penetrating and others were not, and in some the-financial basis, and it was hoped that the pathological laboratory would " keep alive that glow of intellectual vitality which medical education inspires, and constitute a centre to irradiate the remoter hospitals for the insane in Scotland."

The thirty-second annual report of the Asylums Research Laboratory for 1928 shows that the objects of the founders of this scheme are being fulfilled. In addition to routine investigations and visits, the pathologist, Dr. F. E. Reynolds, together with Dr. Logan Turner, has published a number of papers on research, and has made progress with his scheme of establishing a centre of neurology in Edinburgh University. Among the lecturers at the 1928 annual course on neuropathology was the first assistant pathologist, Dr. David Orr.

VAGINAL EXAMINATION IN THE THIRD STAGE OF LABOUR.

If there is one guiding principle in midwifery that has been generally accepted, it is the strict limitation of all internal examination and manipulation because of the risk of carrying infection from the surface of the body into the genital canal. The anal, perineal and vulval areas cannot be made germ-free, and the tendency in modern obstetric practice has been towards the improvement and development of methods of external examination and manipulation in order to obviate the risk of passing through a germ-bearing area. Hospital statistics prove the reality of these dangers, for morbidity increases with interference and grows greater as this interference extends upwards, reaching a maximum after manual removal of the placenta. Hence any suggestion to increase internal intervention must be very clearly investigated to find whether its advantages to the patient will outweigh its undoubted disadvantages. This applies emphatically to Dr. Morris Leff's[1] advocacy of vaginal examination after the fœtus is born in order to discover if the placenta has separated. His paper is based on a series of 1000 consecutive cases, and contains some useful contributions to our knowledge of the phenomena of the third stage of labour. He rejects the view that retroplacental hæmatoma plays an effective part in the separation and considers that this process follows more promptly on the birth of the fœtus than has been thought. But even if these physiological observations are accepted as accurate, the onus of proof for a change in our management of the third stage of labour lies with the author, and the case will be decided by the justification he can offer for vaginal examinations in the uncomplicated third stage. In almost 90 per cent. of the 1000 cases the placenta was delivered within five minutes of the fœtus, and in all but 24 cases within ten minutes. Manual removal was practised in two cases. The average duration of the third stage in the 1000 cases was 4·3 minutes. There is, therefore, no question that this practice may lead to a considerable shortening of the time of the third stage. That alone could scarcely justify Leff's claims; further reasons are given in a considerable reduction in loss of blood and, in consequence, of morbidity, and that the patient recuperates sooner. For these statements, however, no evidence is offered beyond that of a diagram showing the placenta obstructing the cervix, blood accumulating behind it, and no sign of bleeding externally; 267 cases showed bleeding before delivery of the placenta, while 733 gave no evidence of bleeding, from which it seems to be taken for granted that this blockage by the placenta, as shown in the diagram, occurred in nearly three-quarters of his cases. There is also a table giving the estimated loss before and after delivery; in 712 cases it was said to be slight (under 6 oz.); in 243 moderate (between 6 and 12 oz); in 41 considerable (up to 20 oz.); and in 4 profuse (over 20 oz.). There are no morbidity records, and no clear proof that the finger passed into the cervical canal can accurately determine all the points which Leff mentions, such as " where the placenta is located after separation," a knowledge of which he regards as essential to a proper technique in expression. He may have had success with his method, but before recommending it for general adoption he must show that his cases have at least no greater morbidity than those under the method hitherto found satisfactory. This gap deprives his contribution of much of the practical value it might otherwise have had

THE UNITY OF STREPTOCOCCAL TOXINS.

In the early days of streptococcal history—and so quickly has knowledge increased that one is apt to forget that its history began in the 'eighties—there was a tendency to believe that organisms recovered from different lesions in the body were each specific and distinct bacteria. The widespread nature of streptococcal infection threw doubt on this theory, and the swing of the pendulum led to the theory, still prevalent in France, that there was only one streptococcus. To-day opinion is half-way between these extremes. The animal streptococci, the fæcal streptococci, are held to be distinct strains. The hæmolytic strains differ from the non-hæmolytic, and the former are the more virulent organisms, though mutation from one form to the other occurs. But within the group of hæmolytic organisms are three well-known types associated with scarlet fever, erysipelas, and puerperal sepsis. It is urgently necessary to discover whether these are identical or separate, both from the point of view of the ætiology and prevention of the conditions, and of their serum therapy. The method by which serums are prepared may be all-important. The old type of serum employed for treatment of streptococcal infections was known as polyvalent antistreptococcal serum. It was made by injecting horses with suspensions of streptococci, and, therefore, was mainly an anti-*bacterial* serum; although some specimens may have chanced to contain a certain amount of *antitoxin* no attempt was made to induce the formation of it. On the other hand, the antiserum referred to in Dr. A. B. Rosher's article (see p. 129) is essentially antitoxin, prepared by the immunisation of horses with *toxin* produced by the scarlet fever streptococcus. In the preparation of this serum cultures of streptococcus are injected into the horses as well as toxins, so that it should have antibacterial properties as well as antitoxin ones. The problem is not easy to approach. Agglutination and cultural tests are indefinite, and perhaps inadequate, for the main question to be solved is that of the specific or non-specific toxin production of different strains. And the method mainly employed has been the skin-test technique of G. F. and G. H. Dick, although a few results with rabbits, and a recent paper in this journal by H. Burt-White,[1] on therapeutic effects of scarlet fever serum on puerperal sepsis have been recorded. Results are remarkably discordant. D. G. S. McLachlan[2] found erysipelas toxin to be neutralised by scarlet fever antitoxin. H. Burt-White found puerperal fever to be beneficially treated by scarlet fever antitoxin. G. F. and G. H. Dick,[3] however, recently published an elaborate analysis of the mutual action of erysipelas and scarlet fever toxins and antitoxins. They found no neutralising power whatever of non-homologous sera; moreover, individuals were frequently found immune to the one toxin, while sensitive to the other. Similar results have been obtained by other observers using strains isolated from the throats of rheumatic children. In all these cases human skin tests were used. Among other authorities who found results opposite to those of G. F. and G. H. Dick, are C. C. Okell and H. J. Parish,[4] who could find no distinction between any streptococcal toxins. Dr. Rosher, in the paper already referred to, has obtained remarkably successful results in four patients with septicæmia, blood cultures being positive in all cases. The identity of skin reaction with toxin is by no means proven. Since it is now established that concentrated toxin will kill laboratory animals, it would appear reasonable to use that method in differentiating the toxins. Our only specific means of dealing with streptococcal infection at present is with antitoxins. Their effect on animals is dramatic, in the neutralisation of toxin, and the prevention of death, or at any rate its prolonged delay, in infection with living organisms. If there is more than one toxin, we must look to serological laboratories for the appropriate antisera. And, since the only hope of any serum therapy lies in its earliest possible use, some rapid and certain method of recognising strains becomes essential. Meanwhile the practitioner who receives a report that a hæmolytic streptococcus has been recovered from the blood of a patient suffering from septicæmia will be wise if he injects scarlet fever streptococcal antitoxin in preference to antibacterial serum.

THE ÆTIOLOGY OF ERYTHEMA MULTIFORME.

Erythema multiforme (Hebra) takes a prominent place among the dermatoses which most authorities in England and America have accepted as examples of the effect of focal sepsis. The work of Rosenow on the variable toxicity of streptococci, and the clinical observations of Leslie Roberts and H. W. Barber in this country, have gone far towards establishing this hypothesis, but in practice it is found that extirpation of accessible septic foci is by no means always successful in preventing recurrences of the clinical manifestations, even when autogenous vaccines are associated in the treatment. A paper[1] just published by Prof. Edwin Ramel, of Lausanne, is of great interest in this connexion. He admits many of the contentions of those who argue in favour of a streptococcal ætiology; thus he agrees that sore-throat often precedes the eruption and that hæmolytic streptococci can sometimes be recovered from the lesions. But he quotes cases in which these organisms were not found, and claims that if erythema multiforme has a streptococcal cause the organisms should always be present in the skin, for they are always recoverable in the true streptococcides. The argument is not altogether sound, for there are undoubted cutaneous manifestations of syphilis and tubercle in which all efforts to find the virus in the skin have been fruitless. The phenomena of skin sensitisation are highly complex, however, and Ramel cannot accept a theory of special streptococcal susceptibility of the skin in erythema multiforme on the evidence at present available. He has attacked the problem —which in its salient features much resembles that of lupus erythematosus—in another way. Being convinced of the tuberculous origin of lupus erythematosus he was led to suspect a similar ætiology for erythema multiforme, and in four cases—previously unpublished—he claims to have demonstrated a "tuberculous bacillæmia at the period of eruption." His technique is briefly as follows. About 5 c.cm. of the patient's blood were injected into the subcutaneous tissues in the region of the left groin of two guinea-pigs. These animals seemed to show no signs of ill-health for three months after the inoculations, but necropsy then revealed a little enlargement of the local lymph-glands and some greyish gelatinous nodules in the lungs. A tissue extract from them was made into a second series of guinea-pigs, with a somewhat similar result after two and a half months. Yet a third series was then subjected to the same experiment, and in these the clinical evidence of tuberculosis was very strong, and the suspicion was amply confirmed by the microscopical demonstration of acid-fast bacilli in smears of tissue fluids from the various organs. A similar result was obtained in all four cases of the disease. In his commentary Prof. Ramel is careful to anticipate various criticisms to which his observations will give rise. The findings, he says, were unexpected even by himself, and he agrees that patients with erythema multiforme rarely, if ever, manifest any clinical signs of tuberculosis. The question of the validity of the method of successive inoculations and the possibility of "spontaneous" tuberculosis in his stock are discussed and balanced against the remarkable concordance of results in the four cases. It is claimed for tubercle that it explains the symmetrical distribution of the eruption, the occasional occurrence of fatal cases, and the sudden onset, sometimes after additional factors have been brought into play—such as erythema solare or an illness or septic condition. His theory would allocate to the streptococci the rôle of "agents provocateurs," rather than "origines malorum," and from the dermatological standpoint it is, to say the least of it, disconcerting. If confirmed it would profoundly modify current views on the ætiology of this dermatosis, and also (as the author himself observes) the present conceptions of the general pathology of tuberculosis.

REMOTE PROGNOSIS OF PNEUMONIA.

FOR many years it has been recognised that children who have had a long respiratory infection are extremely liable to develop pulmonary fibrosis and bronchiectasis, with distressing symptoms. This fact led Dr. H. P. Jameson[1] to investigate the after-history of children who had had pneumonia in the Hospital for Sick Children, Great Ormond-street, London, and in the Children's Hospital, Birmingham. Fifty-eight children whose illness had lasted more than three weeks were re-examined after a considerable interval, and of these 18 were found to be suffering from symptoms severe enough to make them lead a life of semi-invalidism. Those who had rickets as a complication at the time of their infection did worst, whereas even out of those 23 who had what the author calls an acute non-specific pneumonia (as opposed to one following measles or whooping-cough) four, or 17 per cent., had severe symptoms of pulmonary catarrh. This statistical study, small as it is, emphasises the problem with which the physician is frequently faced in an out-patient department. A child may be discharged from a ward having made an apparently satisfactory recovery from a prolonged bout of pneumonia, or may even return from a month's convalescence in the country, only to be found suffering from incipient bronchiectasis or a second attack of pneumonia. Dr. Jameson's experience should lead to a more serious consideration of these cases; strong efforts should be made to prevent the development of sequelæ, since the patients are likely to reach a stage of danger not only to themselves but to the other members of the families to which they belong. It is not improbable that if they were examined regularly in follow-up clinics that the proportion of children whose lungs are permanently damaged might be found even greater than that recorded by Dr. Jameson. An attempt should be made to reduce it by earlier recognition and treatment. It has long been a matter of regret that no sanatoriums are provided for chronic non-tuberculous cases, since much can be done by open-air treatment to minimise the damage done to the lung. These children benefit greatly by a visit to the country, and this benefit is often of long duration. Radiographic evidence supports the belief that the fibrous changes when present can be arrested. Unfortunately it is usually impossible for children of the hospital class to spend much time in the country. If their stay has to be limited, it is desirable that the winter rather than the summer months should be chosen for life in the country. As regards other treatment, ultra-violet ray therapy can be tried, and vaccines help to clear up the lung in a small proportion of cases. Almost without exception the adventitious sounds are heard at the bases of the lungs in these post-pneumonic patients. This in itself suggests mechanical treatment for their relief, and although it is early to judge fully of massage, it appears to assist in promoting convalescence. Many of our hospitals are trying out this comparatively recent innovation; Dr. Douthwaite and Miss Angore have given pulmonary diseases a prominent position among the indications for treatment by massage and gymnastics discussed in a recent paper.[2] They stress the importance of the expiratory part of respiration, and although they desire a large expansion they do not wish to gain it at the expense of the alveolar walls with risk of emphysema. It is essential to carry out exercises in such a posture that the patient has the assistance of gravity in helping him to expectorate the pent-up sputum. It is surprising with what speed youngsters will learn these exercises, and with what enthusiasm, according to their mothers, they will do them in their own homes. It is by these measures rather than by medicine that we can hope to prevent recurrences, which, as Dr. Jameson has shown, increase the chances of severe sequelæ to 50 per cent. There seems to be no definite criterion as yet whereby we may discover which among the non-pleurogenous patients is going to develop symptoms, and therefore it is wise to treat them all as potential cases of pulmonary fibrosis.

ALCOHOL AS AN ECONOMIC FACTOR.

Sir Josiah Stamp's lecture[3] to the Society for the Study of Inebriety will certainly do something to discourage facile statements on the economics of alcoholism. Most of us have lived too long to need his advice to be chary of believing all we are told about prohibition in America, but it is easy also to be misled by statistics from nearer home. For instance, one of the arguments against the brewing trade is that it finds employment for very few workers in comparison with the money it receives from the public. Sir Josiah quotes a plausible series of figures published by a temperance journal to prove this point, but remarks that they ignore those persons employed in distribution, in producing current materials, and in manufacture of articles necessary for repair and maintenance of the plant. Their inclusion, he says, would raise the numbers approximately to the standard given for other trades. Further, one has to consider the revenue obtained from the drink duty, which is used for the employment of persons in Government service. And the fact must be faced that under prohibition the loss of revenue to the country from this source would have to be supplied by increased general taxation.

Although it is extremely difficult, as Sir Josiah Stamp says, to arrange any experiment which will demonstrate the effects of removal of alcohol upon workers, uninfluenced by other factors, a large number of observations made under varying conditions must carry a certain amount of weight if their results tend to agree. To give an example from the United States, Prof. Feldman's questionaire on Monday and after-pay-day absenteeism produced, out of 287 replies, 184 reporting considerable improvement since the introduction of prohibition. Of these 184, 88 gave most of the credit to the Act, and 40 gave it part of the credit; 83 had had no problem of this kind before or since. Similar investigations on liability to industrial accidents brought 223 replies; 112 reported no change, 47 a large reduction chiefly or partly due to prohibition, 27 a small reduction, and 41 reductions due to other causes. Prof. Feldman, in summarising these results, says: "The most definite fact is that over a fourth credit prohibition with reducing accidents due to liquor, while not a single person asserts it made accidents more frequent." In Great Britain a progressive improvement in accident statistics has run pari passu with a decline in drink consumption, but the connexion is only inferential. With regard to the actual effect on industry, President Hoover in 1925 said that direct comparison of production efficiency before and after prohibition gave an increase of 10 per cent. in output. A firm of electrical engineers, who some years ago decided to run on total abstinence lines, averaged lost time at one-half of 1 per cent., where elsewhere in this trade the figure averaged 10 per cent.; and where returns for firms with 100,000 workers gave an average of 5 per cent. for lost time for sickness and accidents, this firm's figure was 1·4 per cent. Though none of these instances is definite proof of trade improvement due to removal of alcohol, their tendency is obviously in this direction. In discussing crime caused by alcohol, Sir Josiah gave it as his opinion that the economic cost of crime, as measured by the loss of productive output of the criminal, is not high. The number of persons leading a *life* of crime is comparatively small, and these, if successful, are seldom excessively alcoholic. Crimes due to alcohol are usually acts of impulse and violence, and the performers are commonly full producers as ordinary citizens. To the loss of production during imprisonment, which is relatively small, must be added the withheld products of the chronic alcoholics. He also distinguished between the actual loss to the country by absence of production, and the distribution for relief of these persons of funds which might be otherwise employed; this expenditure does not represent a loss of wealth, but only a maldistribution of wealth already produced. The only true loss is the loss of production on the part of persons incapacitated by alcoholism. There remain, however, the economic costs of dealing with criminals —expenditure on police, justice, gaols, &c.—and these are high.

In summarising his views on the effect that suppression of alcohol would have on economic output, Sir Josiah said: "The whole matter may be summed up by my saying that those who put the economic difference at less than 8 per cent., and those who put it at more than 15 per cent., both speak against the weight of the evidence."

MORE NEWS ABOUT DICHOTOMY.

A FORTNIGHT ago the *Newcastle Journal and North Star* gave its readers in Newcastle and elsewhere lurid tidings through the London correspondent of the paper who has reason to believe that a number of "Harley-street specialists" have developed the practice of giving general practitioners a portion of the fee charged to the patient. Further, he finds that "the Harley-street man . . . is confronted with a growing demand that he should return half the fee" to the general practitioner, whether or not he has personally attended the consultation or operation. This is described as a growing demand. We certainly ought to be scared by this picture, and assuredly we should be if our experience coincided with that of the writer of the paragraph. We should reflect that the general practitioner may become less rapacious or the specialist less pliable. Otherwise it would seem inevitable that the specialist will soon have to hand over the whole of his guineas to the recommending doctor, with the hope that the latter may be generous enough to refund him something. The London correspondent may infer correctly that consultant fees will be increased, but the increase will not be due to the situation which he suggests—namely, that the consultant is beginning to feel a shrinkage in his income, because if he will not pay the bribe no doctor will recommend him, while if he pays it his earnings may be halved. Impaled upon the horns of a dichotomy, such an one would deserve our pity, but the character belongs to fiction. Some time ago there was considerable discussion of the alleged practice of secret fee-splitting. Concerning its ethical and legal aspects there is no need to add anything to what is said of it in "The Conduct of Medical Practice." If, however, any member of the public in Newcastle or elsewhere now fears the worst, he may yet think it worth while first to await the production of more evidence than has hitherto been vouchsafed. If he believes that, next time he has occasion to use the services of a specialist, he will find the fees automatically doubled by some corrupt bargain on the part of his family doctor acting as his trusted agent, he might ask the latter to tell him the truth.

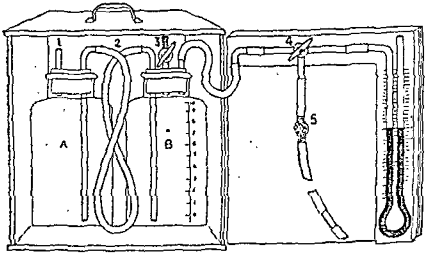
AN IMPROVED ARTIFICIAL PNEUMOTHORAX APPARATUS.

Of the various forms of apparatus used in artificial pneumothorax, the original Lillingston-Pearson still appears to be the simplest, cheapest, and most generally used. E. H. Stokes and A. J. H. Stobo,[1] by introducing some minor modifications, have made it simpler and more practical. They say that in the original apparatus the clips are unsatisfactory in that they are apt to become worn and to slip, thus allowing air-leaks to occur, and that there are too many of them. For the proper working of the clips, thin-walled rubber tubing is necessary, and in time it becomes flattened, tending to interfere with the flow of air. They also maintain that the arrangement of the tubing is clumsy. To overcome these disadvantages, and to make the apparatus more portable, they have arranged that the box (see figure) shall be 12 in. high, 9 in. wide, and 6 in. deep. A three-way glass tap (4) attached to the door of the box controls the air passing from the bottle (B) to the patient, and to the manometer. The manipulation of the air-flows is thus simplified, and the wings of the glass cock, on which is a small black dot, indicate the direction and patency of the air channels. If desired, the tap may be turned in such a way that all three channels are shut off, as shown in the diagram. In order to allow the refilling of bottle (B) with air, a glass tube packed with sterile wool and fitted with a two-way glass tap (3) has been inserted into the cork. Thick rubber tubing is used throughout. The authors say that they have used the modified apparatus in their work with complete success during the past five months.



We regret to announce the death of Sir George Dancer Thane, professor of anatomy at University College, London, from 1877 to 1919, and later a chief inspector for the Home Office under the Cruelty to Animals Act.

INDEX TO "THE LANCET," VOL. II., 1929.

The Index and Title-page to Vol. II., 1929, which was completed with the issue of Dec. 28th, is now in preparation. A copy will be sent gratis to subscribers on receipt of a postcard addressed to the Manager of The Lancet, 7, Adam-street, Adelphi, W.C. 2. Subscribers who have not already indicated their desire to receive Indexes regularly as published should do so now.

The Clinical Interpretation of Aids to Diagnosis.

A Series of Special Articles contributed by Invitation.

LIX.

SIGNIFICANCE OF THE BLOOD CALCIUM.

Part I.*

Calcium is essential to the normal metabolism of all living organisms. It enters the body via the food, is absorbed through the alimentary canal, exists at a more or less constant level in the blood stream, is stored in the bones, and is excreted via the urine and the fæces. While calcium has been used in some form or another as a therapeutic agent for a very long time, within recent years, following the development of the technique of blood estimations, a more definite rationale for treatment has been evolved. The metabolism of calcium is intimately related to that of phosphorus, and both play a prominent part in the growth of the organism. The study of the changes in calcium metabolism is thus important in many infantile disorders. Interest has been further roused in the metabolism of calcium through the preparation of an active parathyroid extract, which possesses the property of increasing the blood calcium even in normal animals.

In health the blood calcium content is remarkably constant—at a figure between 9 and 11 mg. per 100 c.cm. of serum. Evidence has accumulated to show that about 60 per cent. of the calcium in the blood is in a diffusible form and 40 per cent. is non-diffusible. This non-diffusible fraction is more fixed, and probably is combined with protein, while it has been shown that the diffusible portion supplies the free ionised calcium. Electrometric determinations have shown that the serum contains only about 2 mg. per 100 c.cm. of free calcium ions. Symptoms of calcium deficiency are present when the ionisation of this amount is impeded, and when the amount of the diffusible fraction is low. This has been the explanation put forward when a low total blood calcium is found in patients who do not show any signs of a calcium deficiency—that although the serum calcium in toto is low, the diffusible fraction is not affected in the same degree, and in consequence the active fraction is within the normal range of 2 mg. On this view no dogmatic statement can be made, for the technical difficulties in determining the accurate proportion of these two fractions in the blood serum are such that sufficient analytical data have not been produced. Until more reliable and easier methods come into general use, views upon these diffusible and indiffusible fractions have to be accepted with limitation.

The ordinary estimation is performed on the blood serum, a quantity of 2 c.cm. being sufficient. The principle of the method is the precipitation of the calcium as calcium oxalate by the addition of a known amount of ammonium oxalate. This precipitate is freed of all excess of ammonium oxalate by washing with ammonia and then dissolved in sulphuric acid. The oxalic acid liberated is then titrated with a dilute solution of potassium permanganate. The method is reliable, and yields in experienced hands very constant results.

Factors which influence the calcium metabolism and the level of serum calcium are the amount of calcium ingested with the food, the amount of calcium absorbed through the gut, and the proper control exerted by the secretion of the parathyroid gland. Undoubtedly there are other factors, but it is well known that when the food ingested is free of calcium tetany occurs and the blood calcium falls. It is also a fact that in rickets there is a great loss of calcium in the fæces, and it is believed a deficient absorption from the intestines, with a corresponding low value of calcium in the blood serum. Again, when the secretion of the parathyroid gland is absent, low calcium values are observed, and symptoms of calcium deficiency are manifest. Provided therefore that the diet is adequate in calcium, that the alimentary tract is able to absorb a sufficiency, and that there is no defective function of the parathyroid glands, it appears that the blood calcium will be at a normal value, and no signs of calcium deficiency observed. There are one or two reservations to this statement, for exceptions are seen. The ratio $\frac{\text{Na}+\text{K}}{\text{Mg}+\text{Ca}}$, first pointed out by Loeb, which draws attention to the opposite effects of the two groups of elements, may explain how symptoms resembling a calcium deficiency may be present and yet the calcium be found to be within normal limits. If the sodium in the serum is increased at the expense of the calcium signs of tetany may occur, as is seen when sodium phosphate is given to cases of latent tetany; when whey supplants milk in the infant's dietary, electrical hyperexcitability may be demonstrated, although the blood calcium be found at a normal level. The high Na content of whey is regarded as being the factor disturbing the balance of $\frac{\text{Na}}{\text{Ca}}$ and resulting in a latent tetany. Again, it often happens that a low blood calcium is encountered in cases which do not show any active or latent tetany; such examples are found in nephritis, renal rickets, and the adult form of uræmia. The explanation offered for this apparent anomaly is that a state of acidosis exists, and any process which tends to produce an acidosis increases the ionisation of calcium—so that although the total calcium value may be low the ionised fraction is within the normal limits. Any reverse state such as alkalosis produced by the ingestion of excessive doses of bicarbonate, persistent vomiting of acid juice, or hyperventilation of the lungs (with washing out of CO_2), may result in tetany, but with no diminution of serum calcium. The explanation offered here is that the ionisation is impeded by the alkalosis present. Although no definite proof has been produced, this dependence of ionised calcium on the acid-base equilibrium is interesting, and certainly furnishes a more complete explanation of the various types of tetany.

---

[1] Med. Jour. Australia, Nov. 2nd, 1929, p. 610.

* Part II. will appear next week.

Hypocalcæmia.

Any value of blood calcium below 9 mg. per 100 c.cm. is regarded as within the pathological range. Rarely does the value fall below 4 mg. Symptoms are frequently present when a value below 8 is obtained, and almost invariably when the calcium is less than 6 mg. per 100 c.cm.

Tetany.—The main disturbance and most obvious in all conditions in which there is a fall of calcium, acute or chronic, is that called tetany—the name given to the clinical condition in which hyperexcitability of the neuromuscular apparatus is the essential basis. All gradations of severity from the acute form with convulsions to the mild and latent, with only an increased irritability to galvanic stimulation, are encountered. In the acute form the calcium may fall to a level of 5 or 4 mg., but when the condition has existed for some time, although the calcium may still remain within the low range, the symptoms of active tetany are absent. It seems that the body is able in time to adjust itself to this abnormal level, although active tetany may be precipitated by œstrus in dogs and menstruation in human subjects; pregnancy is certain immediately to convert a latent into an active tetanic state. This hypocalcæmia can always be relieved by the administration of calcium salts, either rapidly by the intravenous route or more slowly by the ingestion via the alimentary canal.

The conditions in which hypocalcæmia is found are spasmophilia, rickets, renal dwarfism, cœliac disease, osteomalacia, parathyroidectomy, and renal disease. These conditions, and also that of hypercalcæmia, will be considered next week.

ANTI-TUBERCULOSIS WORK IN THE COUNTY OF LANCASTER.

Dr. G. Lissant Cox's report for 1928 shows clearly that the medical staff of the county are alive to the need for research into the prevention and treatment of tuberculosis, especially research for which a large county area provides exceptional facilities. The county council have encouraged the tuberculosis medical service to give trials to the various new methods of treatment which are, from time to time, recommended as "cures" for tuberculosis, provided, of course, that there are patients prepared voluntarily to coöperate. A sum of £200 per annum has been voted for the purpose, and since the resources of the county scheme (services of staff, use of premises, laboratory facilities) are available without charge against the research fund, and new preparations are often offered for trial free of charge, the sum has gone a long way.

In addition to testing new remedies, the medical staff have analysed the histories of 1486 children under five years of age, living in 1003 homes, in each of which there were one or more adults suffering from tuberculosis. There was no selection of cases by tuberculosis officers, and no undue proportion from any particular area or areas. Of the children dealt with in this research, the substantial majority remained, throughout their period of observation, in constant contact with an adult tuberculous case in their homes, after allowing for those adults who received several months institutional treatment and for a small number of children who were removed for varying short periods to the homes of relatives. The death-rate from non-pulmonary tuberculosis of children exposed to risk in tuberculous households from an adult with positive sputum was found to be greatly in excess of the general rate from the same cause in the county—nine times greater in the age-group 0–1, 14 times greater in the age-group 1–2, and 19 times greater in the age-group 2–5. This great excess of non-pulmonary tuberculosis was mainly due to deaths from tuberculous meningitis which accounted for two-thirds the mortality in the non-pulmonary group, ages 0–5.

Similarly (although statistically insignificant owing to the probable error due to chance) the death-rate from non-pulmonary tuberculosis of children exposed to risk in tuberculous households with an adult case or cases suffering from pulmonary tuberculosis with negative or no sputum, was also in excess of the rate from the same cause among children in the county, the rate being three times greater in the age-group 0–1, four times greater in the age-group 1–2, and ten times greater in the age-group 2–5. The number of deaths from pulmonary tuberculosis of children exposed to risk in tuberculous households was too small to justify any conclusion. The mortality-rate from tuberculosis was greater amongst the children of tuberculous positive sputum mothers than fathers. It seems that Calmette's calculation, that in France 24 per cent. of the children of tuberculous mothers die from tuberculosis in the first year of life if left with the mother is many times higher than the Lancashire experience. The latter shows that the death-rate from tuberculosis for corresponding Lancashire children was 3·2 per cent.; from all causes the rate was only 11·5 per cent. Further, the Lancashire investigation shows for children observed from birth to four years of age a death-rate, from tuberculosis and from all causes, a little lower than the French figure for children observed from one month to four years vaccinated with BCG; and much lower than for the French children unvaccinated with BCG.

Taking a period covering the whole first five years of life, those children who were in contact at home with an adult person suffering from pulmonary tuberculosis (whether sputum positive or negative) did not have a *higher mortality* from *all* causes when compared with the expectation of life of children in England and Wales. Full details of this work are embodied in a special report, issued by the county, which was also reprinted in *Tubercle* for August of last year.[1]

REPORTS OF MEDICAL OFFICERS OF HEALTH.

THE following are some 1928 statistics of nine districts, varying in local government status:—

Name of district and estimated (R.-G.) mid-year population.	Birth-rate.	Death-rates per 1000 of the population.					Death-rates per 1000 births.		
		All causes.	Tuberculosis.	Cancer.	Respiratory diseases with influenza.	Heart disease.	Infant and neonatal mortality.	Young child (1–5 yr.) mortality.	Maternal mortality from childbirth.
Bolton C.B. . . (181,200)	14·3	12·8	0·77	1·35	2·4	1·7	64/26	37	3·1
Kensington M.B. . . (178,200)	14·3	13·0	0·74	1·78	1·9	2·4	83/27	49	2·7
Willesden U.D. (176,589)	15·1	9·8	0·71	1·36	1·5	1·6	57/27	27	3·7
Isle of Ely County . . (77,780)	19·3	11·7	0·92	1·80	1·5	1·9	59/—	25	4·0
Cambridgeshire . . (72,440)*	15·5	12·6	0·76	1·85	1·5	2·2	62/—	15	5·3
Cambridge B. . (60,860)	12·8	10·9	0·80	1·74	1·6	1·3	55/29	23	2·6
S.-W. Kent United Health Area . . (81,756)	14·0	12·6	0·77	1·90	1·4	2·4	48/—	—	0·9
Chesterfield R.D. . . (85,000)	21·0	10·0	0·76	1·06	1·6	1·2	76/—	—	3·3
Hereford R.D. (13,320)	16·6	11·0	0·75	1·05	1·5	2·0	36/18	—	4·5

* Excluding Borough of Cambridge.

Relation of stillbirths to live births: Kensington 2·6 per cent. (N.). Willesden, 3·5 per cent. (R.). Cambridgeshire, 2·6 per cent. (N.). Cambridge, 4·6 per cent. (N.).
N. = notified. R. = registered.

Bolton.

Dr. C. W. Paget Moffatt shows that the infant mortality-rate was ten less than it has ever been before in Bolton, and that the neonatal rate, which is usually high in Bolton, was also lower than ever before. The rate for the latter (26) may be compared with an average rate of 39 for the ten years 1918–27. The maternal mortality-rate was also comparatively satisfactory. The Haslam maternity home (18 beds), a fine building situated in pleasant and extensive grounds and presented to the town by the late Mr. J. P. Haslam, is much appreciated. Over 300 cases were admitted for confinement, and all expectant mothers on the admission list attend the antenatal clinic, except those who are having antenatal care from their own doctor. Another municipal antenatal clinic was attended by 130 patients, the total number attending both clinics being 444, whilst the births numbered 2593. Dr. Moffatt is of opinion that, according to Bolton experience, the recent apparent increase of cancer in females is confined to growths in inaccessible sites, and that most of the apparent increase in males is also due to more accurate diagnosis.

The Bolton corporation now own the whole of the gathering grounds of their water-supply, and all but five of the farms thereon have now been evacuated, and arrangements have been made to deal with the remainder during the course of the next few years.

---

[1] See also THE LANCET, 1929, i., 1201.

Bolton still has 2816 pail-closets and 1840 privy middens needing conversion or demolition. Of the 43,000 water-closets, 15,000 are of the "waste-water" type. The permissible limit for black smoke is two minutes in the half hour but bursts of dense black smoke for periods of less than 30 seconds are not counted. Dr. Moffatt states that no stricter standard is adopted in the Manchester area. In Sheffield, however, the limit for a chimney serving one boiler furnace is two minutes in an hour's observation, with no exception for short bursts, and apparently the Bolton chimneys had no difficulty in conforming to their more lenient standard, as out of 642 half-hour observations there was only one emission exceeding two minutes. The number of new houses erected dropped from 1081 in 1927 to 479 in 1928. Out of the 479 there were 416 subsidy houses, 160 municipal, and 256 by private enterprise. In order to facilitate the clearance of slum areas, Dr. Moffatt suggests that houses might be built in a central position, to be tenanted in turn by the inhabitants of the various slum areas during the period of reconstruction, and also that poor class property might be purchased, renovated, and used in the same way. At the time of writing, by-laws for houses let in lodgings urgently needed are awaiting the approval of the Ministry. The charges made for these rooms are "in many cases grossly exorbitant," and the amenities provided are "miserable." Dr. Moffatt would also like to see two-roomed dwellings provided for childless elderly married couples or married couples whose children have left them, as such people are an important factor in the slums, whose needs are not catered for by private enterprise. There are 129 cow-keepers in the borough, and the cows kept number 2725. One farmer has a licence to produce Certified milk. During the year five cows were found to be giving tuberculous milk and were dealt with under the Order. One farmer was fined £10 for failing to notify a cow suffering from tuberculosis of the udder.

There were 13 notifications of encephalitis lethargica and 11 deaths; 3 of the patients who died had not been notified. Dr. Moffatt comments on the lack of suitable provision for the after-effects of this disease. There were 840 notifications of scarlet fever with 1 death; 465 were admitted to hospital, "where all cases which are not quite definitely mild receive the scarlet fever antitoxin, the effects of which are really wonderful." There was no death in hospital, but an unusual number of cases of otorrhœa, and Dr. Moffatt thinks such complications of scarlet fever are apt to occur in cycles. Dr. Mary Boullen, who conducts the light clinic, found that long-continued attendance, with moderate exposures, gave better and more permanent results than attendance over a short period with more rapidly increasing exposures. She thinks that, taking everything into consideration, the clinic continues to justify its existence, and that the mothers who attend regularly are appreciative of the improvement in the condition of their children and are satisfied with the results of treatment.

Kensington.

Dr. James Fenton reports that the rheumatism supervisory clinic, established towards the end of 1927, has made good progress. A report on the first year's working, published as a separate document, shows that much research has been initiated, both from the environmental and the clinical points of view. There were 159 notifications of acute rheumatism during the year ended Oct. 1st, 1928, and of these 81 were seen at the centre, in 8 of whom the diagnosis was not confirmed, and in 6 of whom it was doubtful. A series of 200 cases has come under review, and the study of the prevention of relapses has made a good start. Dr. R. C. Lightwood, who is in charge of the clinic, was granted six months' leave of absence in order to undertake special work at another hospital, and his position has been temporarily filled by Dr. Francis Bach. The comprehensive municipal tuberculosis scheme has not been materially altered since it was adopted seven years ago, and includes among its features a very representative "care" committee and efficient arrangements for following up suspects and contacts. Dr. Fenton is able to report that the decline in the death-rate from tuberculosis still continues. During the first three years of the last decennium the death-rate per 100,000 from all forms of tuberculosis was 131, 109, and 105; during the six years, 1922–27, the rates were successively 95, 85, 83, 89, 89, and 80, and during 1928 the rate for the first time got into the seventies.

An unsatisfactory feature of 1928 was the rise in the infant mortality-rate from 68 in 1927 to 83. Dr. Fenton attributes this rise very largely to measles, to an increase in premature births, and to an increase in illegitimate births. Since the war the three years with the highest infant mortality—namely, 1921, 1925, and 1928—have been those with the highest number of illegitimate births. Kensington includes a large population of unmarried women, and in the southern half there are two female for every male elector. There is a large number of unmarried female shop-assistants and domestic servants. In 1928, 9·4 per cent. of the births in Kensington were illegitimate, and accounted for 23 per cent. of the infant deaths. Out of the total of 213 infant deaths, 52 occurred in the first week of life, and 70 in the first four weeks; whilst out of the deaths of the 51 illegitimate children 17 died in the first week and 31 in the first four weeks. In 1928 there were 2559 births in Kensington, and it is estimated that 443 occurred in families financially outside the scope of the council's M. & C.W. scheme. In respect of the remaining 2116, 1456 of the expectant mothers attended the special antenatal clinics held at Queen Charlotte's Nurses' Home and other institutions. This means that 70 per cent. of the expectant working-class women receive antenatal treatment, but Dr. Fenton is not satisfied with this percentage, and expects to increase it. Dr. Remington Hobbs, the borough's consultant gynæcologist, has accepted the duty of investigating for the Ministry every case of puerperal fever and each maternal death.

Pneumonia and broncho-pneumonia, mainly associated with the widespread outbreak of measles at the beginning of the year, were responsible for 59 infant deaths. The heaviest incidence of the London outbreak of paratyphoid fever was felt in Kensington, where 66 cases were notified between July 25th and Sept. 1st. Only one death was attributed to this cause during the year. During the course of the epidemic statements appeared in the press that if the addition of boric acid to cream had still been permissible the epidemic might not have occurred. Dr. Robert Donaldson, the bacteriologist to the borough council, carried out tests from this point of view, and found that even when 4 per cent. of boric acid was added to cream the growth of paratyphoid B in it was not prevented, and 4 per cent. of boric acid is ten times more than the maximum allowed in cream prior to Jan. 1st, 1928.

The Kensington housing problem presents many special features. Thus there are 2091 mews dwellings, and 5690 houses let in lodgings, occupied by several families, instead of by one as originally intended, whilst fortunately the most unsatisfactory form of dwelling—the houses let in furnished rooms—has been decreased from 187 in 1912 to 34 at the end of 1927. There are also 13,000 basements used for dwelling purposes, with ceilings at or below the street level in 640 cases. Unsatisfactory common lodging-houses for women have been closed, and better accommodation provided by private philanthropy and voluntary associations. The council have built about 600 houses and flats, and arranged for the removal of 674 families to the L.C.C. Wormholt Estate, adjacent to N. Kensington. Many trusts have provided blocks of dwellings managed on the Octavia Hill system. Dr. Fenton is able to record great efforts made by the coöperation of the borough council and voluntary housing associations. Cases of overcrowding are becoming less numerous and less difficult to deal with. He points out that legal standards of habitability are necessarily low, and that all is not satisfactory. For example, with few exceptions, the 13,000 basements comply with the legal standards for underground rooms, but nevertheless damage to health must result from thousands of people in Kensington having no living or sleeping rooms other than in basements. Even if new legislation were secured to close the most undesirable of these basements, it could only be enforced very gradually in the absence of accommodation for the persons displaced either in Kensington or outside.

Willesden.

Dr. George F. Buchan mentions that early in the year a large electric generating station extended the use of pulverised coal for steam raising, and that within a short time numerous complaints were received from householders and business establishments as to a serious nuisance from the emission of grit. Observations were made and the grit deposited in trays in the neighbourhood of the works was collected and weighed. As the result of a conference, the company installed grit-arresting and water-screening apparatus, which has lessened the nuisance, but it has been ascertained that another company is about to instal another plant for using pulverised fuel. Immunisation against diphtheria was adopted for the hospital staff in 1926 with satisfactory results, and in May, 1927, Dr. A. G. Troup, the medical superintendent of the municipal hospital, was authorised to offer immunisation at one of the clinics. The bulk of the work in 1928 consisted in establishing the results of the 1927 immunisations, while the advent of fresh cases was disappointing. It is thought, however, that the result of the first year's immunisations will stimulate interest.

Dr. H. Haldin Davis, in his report on the artificial light clinic, shows that many of the patients suffered from vague ill-health, 81 being classed as general debility and malnutrition, and 28 as pretuberculous. Treatment in these cases had satisfactory results, as also in asthma, rickets, and septic skin conditions. The work is handicapped by being carried out "in a draughty underground room of scanty dimensions." Dr. Agnes H. Nicoll, on information from all available sources, concludes that the Willesden school entrant of the last two years has begun school life in much better physical condition and more healthily clad than in 1907. The defects of throat and nose are less grave in degree than formerly, but the condition of the teeth is still far from satisfactory. Functional derangements of the nervous system have not noticeably changed for the better, and the entrant has failed to regain the pre-war level in nutrition. Dr. Bessie R. Mackenzie reports on antenatal work, the first clinic having been established on Nov. 1st, 1916. She describes the essentials of a clinic, and states that it "should be in charge of a competent medical officer—preferably one who has had considerable practical experience in midwifery." One feels that the words "preferably one" should have been omitted. Dr. Alice J. Gray reports on maternal mortality and morbidity in Willesden, 1919–28. During this period there were 123 deaths from childbearing—a maternal mortality-rate of 4·1 per 1000 births. The primary causes of deaths were: sepsis 51, toxæmia 17, hæmorrhage 14, abortion 13, thrombosis and embolism 7, abnormal labour 6, and other causes 15. Of the 13 fatal abortions 3 were criminally induced. The sinister effect of illegitimacy is shown in a table. Thus, during these ten years, for 29,413 legitimate births, there were 115 maternal deaths—a rate of 3·9. Whilst for 962 illegitimate births there were 8 maternal deaths—a maternal mortality of 8·4. In 102 of these fatal cases 33 of the babies were born prematurely, and in 20 of the 123 the baby was stillborn. As regards morbidity, the health of 13,012 mothers attending the Willesden clinics during the 12 months following delivery was investigated, and some morbid condition was noted in 42 per cent. The commonest morbid conditions found were: white-leg, 10 per cent.; breast abscess, 17 per cent.; prolapse, 14 per cent.; perineal tears needing operation, 11 per cent.; and varicose veins, 9 per cent.

Isle of Ely.

Dr. R. French, who presents the report, took over his duties during 1929. The Isle of Ely chiefly uses resident institutions outside the county. Thus five cases of difficult labour were treated at Addenbrooke's Hospital, where also the most used V.D. clinic is held; and 64 tuberculosis patients were sent by the county council to 12 different sanatoriums and hospitals. Great difficulty is experienced in finding institutional accommodation for the various grades of mental defect. About 70 samples of milk are analysed every year, and a curious variation in the average percentage of fat is disclosed. Thus the average fat percentage for 1925 was 3·8, for 1926 3·5, for 1927 3·67, and for 1928 3·85. Items from the districts include: complaints of river pollution by sewage and beet-sugar effluent (Ely U.D.); satisfaction at the relief of unemployment by the sugar-beet factory (Ely R.D.); pollution of the Nene by gasworks washings (March U.D.), and the clearance of a slum area (Wisbech borough). The fruit pickers in Wisbech R.D. are reported to be well housed, and their allotted quarters are inspected just before occupation. A case of encephalitis lethargica was landed from a ship in Wisbech port, and died within a few days.

Cambridgeshire.

Dr. Frank Robinson's report shows that provision for maternity cases was improved by the opening of two new maternity wards to accommodate eight patients in Addenbrooke's Hospital. The county council, however, are still anxious to arrange with the hospital for the provision of a 20-bed maternity home, with an antenatal clinic attached. The council paid for the maintenance of 28 mothers, including sepsis cases, at Addenbrooke's, and also maintained four unmarried mothers at the Ely Diocesan maternity home. In connexion with the latter a babies' home has been recently opened for the reception of infants whose mothers have obtained situations in the neighbourhood. All the 50 midwives who practise in the administrative county are trained women, and through the agency of the County Nursing Association, which is subsidised by the county council, the number of rural parishes without the services of a nurse-midwife has been reduced to 10, with a population of 5738. The county council, having no institution of their own, maintain mental defectives at about 20 outside institutions. A joint scheme with Essex and West Suffolk for adding 34 places to the accommodation has been mentioned since 1924, but has not yet materialised. The county council are of opinion that the public is misled into thinking that Grade A is the highest standard of milk, and ask for the support of all county councils in favour of the alteration of the designations. The only action taken under the Housing (Rural Workers) Act was by Linton R.D.C., which made grants in respect of 16 cottages, all of which were successfully reconditioned.

Cambridge.

Dr. Andrew J. Laird shows that 16·9 per cent. of the births and 29·2 per cent. of the deaths took place in institutions. During the last five years about one-third of the infant deaths have been due to premature birth, and about one-fifth to bronchitis and pneumonia. During the same period there have been five maternal deaths from sepsis and two from other puerperal conditions, giving a maternal death-rate of 1·2 per 1000 births from sepsis, and a total rate of 1·7 from childbirth. Mr. W. B. Grandison's scheme for the dental treatment of mothers and children under the school age continues to grow. Apart from the encouragement of breast-feeding, the essentials laid down by Mr. Grandison are mainly mechanical—e.g., washing the baby's mouth with dilute boric after each feed; the abolition of the dummy and of thumb- and finger-sucking; and the provision of something hard to chew at. After the child has cut four teeth the essentials laid down are: its enrolment in the dental scheme; the purchase of a toothbrush and its use after each meal; the provision of a tooth-cleansing food after each meal; and the bringing up of the child to the clinic every six months. Mr. Grandison states that if these instructions are carried out every child should reach school age free from dental disease. The number of children in their fifth year enrolled in the scheme were 197, and a table shows that they had 3280 sound, 472 decayed but saveable, and 95 decayed and unsaveable teeth. Further, 25 permanent molars had erupted at this age, of which nine were decayed but saveable. Mr. Grandison does not mention whether he is satisfied with these results, but there are no controls outside the scheme. Possibly Oxford might start an opposition experiment founded on the work of Mrs. Mellanby, and giving attention to the food needed for building good teeth rather than to the mechanical side. It is surprising that the choice of tooth-building food should have been ignored in the British mecca of vitamins. The pioneer effort of the Cambridge Housing Society in reducing rentals for large families has made progress. This society has built 45 houses, which are occupied by 45 families, including 200 children. The rents without rates are 7*s.* to 7*s.* 6*d.* a week, with a deduction of 6*d.* a week for each child of school age, down to a minimum rent of 5*s.* per week. The accommodation consists of two living rooms (one being the kitchen), three bedrooms and a bathroom, and a good garden. The society has been encouraged by the results to purchase a new site for the erection of 16 more houses.

South-West Kent.

Dr. S. Nicol Galbraith shows that five isolation hospitals treated during the year 444 cases, and that two small-pox hospitals treated one case. There would, therefore, seem to be room for the pooling of accommodation. There is still a shortage of houses. Tonbridge has 200 applicants on its waiting list, and there is a great shortage at Marden in Maidstone R.D. The position is aggravated by well-to-do people buying old picturesque labourers' cottages, and modernising them for week-end cottages. The administration of the by-laws for hop-pickers has made much demand on the department. Some 60,000 Londoners arrive annually for the hop-picking, and in addition thousands of visitors by train and char-à-banc. Although the arrangements have been improved, there is still need for more careful attention to cleanliness, sanitation, scavenging, and especially to water-supply. Dr. Galbraith gives a photograph of what was a common occurrence during the dry season of 1928—the scene of wreckage left by the burning of huts. More care is needed with regard to the lighting of the huts and to the use of gypsy fires. Three children were burnt to death in 1928. One family brought down a child diagnosed as chicken-pox in London. This led to two cases recognised as small-pox at Marden, which were removed to the M.A.B. hospital. Dr. Galbraith thinks that as this invasion of Kent for three weeks is not like an ordinary holiday problem, the London hospitals should take charge of the infectious cases which arise in the camps. If sanitation were reasonably good, one would expect fewer cases of infectious disease to develop among the 60,000 Londoners while they occupy the camps and lead an open-air life, than if they had lived at home for this period. The infectious cases which developed amongst the immigrants were, whilst picking, diphtheria 7, scarlet fever 3, and small-pox 2; and on return to London: diphtheria 5, scarlet fever 9, small-pox 8, and paratyphoid 1.

Chesterfield Rural.

Dr. Herbert Peck says the crying need of his district is the conversion of privies to water-closets, which is dependent upon another need—that of an improvement in the water-supply. At present much of the water in the gathering grounds of the Northern reservoirs goes to waste owing to the shortage of reservoir accommodation. Additional works are now in course of construction, and the principle of the formation of a joint water board with neighbouring districts has been approved. Coal-mining with quarrying gives employment to nearly half the occupied males in the district.

Hereford Rural.

Dr. R. Wood Power says the industries of the district are almost entirely of an agricultural nature. Hops and fruit are largely grown, and there is extensive breeding of Herefordshire cattle and dairying. Much work is in progress under the Milk and Dairies Order. A detailed report has been made of the premises of 200 applicants for registration, and in only 19 instances did the premises comply with regulations. Existing buildings have been successfully dealt with at 100 farms; 8 new cowsheds have been erected and 22 cooling and milk rooms. Photographs of the cowsheds, before and after alterations, illustrate in a striking manner what can be done by gutting the main structure and providing concrete mangers, floors, and channels, metal stall partitions, and better lighting. Arrangements for hop-pickers are much improved since the by-laws came into force in 1909. About 2500 pickers come from outside the county to 22 farms, as few as 6 going to one farm and as many as 700 to another. They are accommodated in barns, stables, cowsheds, and other outbuildings, and also increasingly in specially erected buildings. Some farms have canteens, but in most cases fresh meat, fish, &c., are supplied from tradesmen's vans, visiting periodically. Illustrated posters supplied by the Health and Cleanliness Council have had a good effect.

The District Council has been made the authority under the Housing (Rural Workers') Act, but, in spite of press notices and the circulation of leaflets, has only had two applications, both of which were withdrawn.

Corrigendum.—In our summary last week (p. 103) of Dr. J. Middleton Martin's report for Gloucestershire, the omission of a sentence at line 45, col. 2, made it appear that the remainder of the paragraph referred to the scheme for the extension of medical services, whereas it actually refers to the totally distinct orthopædic scheme. The work done for the former, in fact, included 12,864 attendances at out-stations and 1515 attendances at hospitals, total 14,379, as compared with a total of 11,460 in the previous year—with a corresponding lessening of the cost per attendance.

INFECTIOUS DISEASE IN ENGLAND AND WALES DURING THE WEEK ENDED JAN. 4TH, 1930.

Notifications.—The following cases of infectious disease were notified during the week:—Small-pox, 248; scarlet fever, 2904; diphtheria, 1695; enteric fever, 38; pneumonia, 1455; puerperal fever, 51; puerperal pyrexia, 97; cerebro-spinal fever, 10; acute poliomyelitis, 6; encephalitis lethargica, 10; dysentery, 6; ophthalmia neonatorum, 88. No case of cholera, plague, or typhus fever was notified during the week.

The number of cases in the Infectious Hospitals of the Metropolitan Asylums Board on Jan. 7th–8th was as follows:—Small-pox, 437 under treatment, 27 under observation (last week 415 and 13 respectively); scarlet fever, 2633; diphtheria, 2701; enteric fever, 28; measles, 824; whooping-cough, 126; puerperal fever, 27 (plus 15 babies); encephalitis lethargica, 121; poliomyelitis, 2; "other diseases," 18. At St. Margaret's Hospital there were 14 babies (plus 6 mothers) with ophthalmia neonatorum.

Deaths.—In the aggregate of great towns, including London, there was no death from small-pox, 4 (1) from enteric fever, 47 (22) from measles, 10 (1) from scarlet fever, 21 (5) from whooping-cough, 63 (18) from diphtheria, 62 (20) from diarrhœa and enteritis under two years, and 64 (11) from influenza. The figures in parentheses are those for London itself.

The 3 deaths from enteric fever outside London all occurred at Newcastle-on-Tyne. Stoke-on-Trent and Wigan each reported 4 deaths from measles, West Ham and Manchester each 3. Cardiff reported 3 deaths from whooping-cough. Diphtheria claimed 4 victims each in Birmingham and Merthyr Tydfil. Of the deaths attributed to influenza 6 were reported from Birmingham, 5 from Bradford.

The number of stillbirths notified during the week was 262 (corresponding to a rate of 37 per thousand births), including 50 in London.

Special Articles.

DENTAL TREATMENT AND NATIONAL HEALTH.

REPORT BY THE NATIONAL DENTAL SERVICE COMMITTEE.

A REPORT issued by the British Dental Association, 23, Russell-square, London, W.C.1, is based on certain unfulfilled recommendations of the Departmental Committee on the Dentists Act (Cmd. 33, 1919), and deals with the dental services which are necessary to the national health under the following heads:—

1. Dental treatment of expectant and nursing mothers and for children up to 5 years of age.
2. Dental inspection and treatment of all children of school age.
3. Dental treatment of adolescents.
4. Dental treatment for all persons insured under the National Health Insurance Act, and for all other adults who are unable to afford dental treatment by private dental practitioners.
5. Dental treatment as an essential element in cases of tuberculosis and of venereal disease.
6. The institution of a coördinated scheme for education in oral hygiene, which would be simple in its application and general in its incidence, but with particular attention to the young, with the object of preventing dental disease.

The suggestions made are in general agreement with the scheme outlined in the Interim Report of the Ministry of Health Consultative Council on Medical and Allied Services (Cmd. 693, 1920). Means are also suggested for the organisation of such dental services, and for the supply of the necessary personnel.

Recommendations.

In brief the recommendations of the Service Committee are these:—

1. That dental treatment be organised at every maternity and child welfare centre.
2. That in the first place the efforts of the profession should be concentrated on obtaining a complete school dental service.
3. That by a suitable scheme of dental treatment for adolescents the complete school dental service be linked up with statutory dental benefit under an amended National Health Insurance Act.
4. That effective supervision and inspection of all public dental services should be carried out by dental practitioners responsible to the controlling authority.

Finally, stress is laid on the importance of education in dental hygiene being consistently emphasised.

KING EDWARD'S FUND.—During the absence of the Prince of Wales in Africa his power as President of the Fund have been confided to a commission consisting of the Lord Chancellor, the Speaker of the House of Commons, and the Governor of the Bank of England.

MEDICAL REFEREES ON INDUSTRIAL DISEASES.

(FROM A SCOTTISH CORRESPONDENT.)

IT is notable what a large proportion of experience in all matters relating to the compensation code for workmen occurs in Scotland. Recently this has been specially observable in the case of miner's nystagmus. The case of Lowe *v.* Wilsons and Clyde Coal Co., decided in the Scottish Court of Appeal and reported in 1930 *Scots Law Times*, 28, makes important reading, for the main point in it applies to the functions of medical referees in all compensation cases based on disablement following on an industrial disease.

The medical referee in that case stated that miner's nystagmus does not necessarily prevent the workman from working underground and drawing full wages; implying a distinction between the date of the commencement of the disease and the date of disablement to earn full wages. It was the failure to make this distinction which tended to create a tangle in the Lowe case. Before the days of compensation in industrial disease cases many nystagmic miners kept on at their work underground, driven by necessity to do so in order to support themselves, their wives, and families. This is still done by determined men, because full wages are more than the compensation allowance.

In these compensation cases based on disablement to earn full wages owing to an industrial disease there is a special sub-code. The workman applies to the certifying surgeon for a certificate that he is suffering from an industrial disease and is thereby disabled from earning full wages. If the certificate is granted the surgeon is to state the date of commencement of disablement if he can; if not, the date of the certificate is taken. Of course, the surgeon may refuse to give a certificate, and then he is not concerned with any date. In either case there may be an appeal to a medical referee. The Act says that, if the referee grants a certificate where the surgeon had refused it, the referee shall fix the date of commencement of disablement. It does not say that, if the referee agrees with the surgeon that the workman is entitled to a certificate, the referee may alter the date which has been fixed by the surgeon. Power "to alter or not to alter," that is the question. There is no judicial decision upon it. It has never even been argued, except in this latest case in Scotland. There have been judicial opinions expressed in England and in Scotland in favour of the medical referee possessing this power, but they are merely obiter dicta, and so is the very definite reasoned opinion to the contrary pronounced by one of the judges of the Scottish Court of Appeal in the recent case. It is worth while to draw attention to the doubt surrounding this question and this latest judicial opinion on it.

The case also has a bearing on the proper way for medical referees to draw up their reports in such cases. They went considerably astray in this respect. The report had to be sent back to the referee to state plainly whether he sustained or refused the appeal from the certifying surgeon, who had found the workman entitled to a certificate. Then the referee added "I therefore sustain this appeal." Even after that, parties were at sixes and sevens as to what the report meant. Probably that was due to the word "therefore," which gave a connexion with preceding matters, some of which was irrelevant and may have been ultra vires. It has to be kept in view that medical men in these cases are not entitled to legal advice, and it is said that the forms supplied to them are the reverse of helpful. Clearly the ordinary professional curriculum should include some degree of instruction in such matters. But the doctor must read the Acts and other documents; he must attend to the specific questions put to him; these he must exhaust; at that point he must draw the line and refuse to step beyond into matters with which he has nothing to do, and which he may not be qualified to deal with. Reasons and reasonings, comments and explanations, including the process by which he has arrived at his decision, will usually be unnecessary and may be damaging.

Neglect of these rather obvious guides may lead to a report being sent back to its author to explain, not a mere detail, but the cardinal point whether the report is "Yes" or "No." That ought to have been found in a few unqualified and unambiguous words in the first line of the report. The history of this case shows that it must be clearly understood what is the question to which an affirmative or negative answer is being given. The reporter appears to have been misled into importing into his functions a question as to the commencement, not of the disablement, but of the disease. Not only so, but there were also in the report words which appeared to express or suggest that the doctor was applying his mind to the legal question whether a previous cash settlement with the workman amounted to compensation in respect of the disablement for which he was now claiming. It is all in the medical man's own interest that his sphere of function in such matters should be as circumscribed as possible. It may well be that he could add much accurate and valuable information and advice, but he is not instructed to do so nor safe in doing so.

MEDICINE AND THE LAW.

Alleged Negligence: Diphtheria Infection.

As a legal correspondent points out on another page, the recent Scottish case of Carmichael *v.* Miller is of considerable interest. Indeed, the issues of fact in the case, in which a series of allegations of negligence against the late Dr. Miller was dismissed by Lord Fleming at the close of last year, are almost as well worth notice as the issues of law.

Duncan Carmichael, a dairyman near Fort William, had a son Duncan, 2½ years old, who on Dec. 31st, 1925, was admitted to the local hospital suffering from scarlet fever. The disease took a normal course till 26 days later, when what appeared to be a secondary attack supervened with sore-throat, pyrexia, and copious rash, desquamation meanwhile continuing. Dr. Miller, medical officer of health for the burgh and medical superintendent of the hospital, and his assistant, Dr. Mackintosh, diagnosed this as a secondary attack of scarlet fever. Another doctor, and also the fever nurse and matron, agreed. The rash was typical scarlet fever rash and none of the clinical appearances of diphtheria was observed. There was otorrhœa, but this was slight and intermittent, and on March 1st, 1926, the child was sent home. Six days later a sister, aged 8, and a brother, aged 7, were notified as suffering from diphtheria and were admitted to the diphtheria ward of the hospital. The girl died; the boy recovered. Another brother was admitted on April 24th suffering from virulent diphtheria; he eventually recovered. The original patient, Duncan, was readmitted on April 24th suffering from a recurrence of otorrhœa, a brushing of which had shown bacilli resembling those of diphtheria. He was kept in hospital till August 3rd, then discharged as cured (the otorrhœa having ceased), readmitted on August 16th on a recurrence of the discharge, removed to Glasgow in November for enucleation of tonsils and adenoids, readmitted at the end of 1926 on a further recurrence of the discharge, and at length finally released from hospital in June, 1927. This long series of illnesses might well have led his father to suppose that the treatment was in some way at fault: he brought his action against Dr. Miller, alleging negligence in various ways. First, it was suggested, the child, when originally discharged from hospital, showed typical post-diphtheritic symptoms, a squint, nasal speech, and unsteady gait. The evidence of these symptoms was vigorously disputed, and the judge held there was no proof of the presence of diphtheria at the date of original discharge from hospital. Lord Fleming therefore decided that there was no negligence on Dr. Miller's part in failing to diagnose diphtheria if the child really suffered from it. The next allegation was that it was negligent to release the patient from hospital while the ear was still discharging. It was proved in evidence that otorrhœa after scarlet fever may continue for years. Lord Fleming said the evidence failed to establish that it was in contravention of the usual or reasonable medical practice to discharge patients suffering from intermittent scarlet fever otorrhœa. He refused to say that Dr. Miller had fallen short of the ordinary standard of professional care and skill in sending the child home before the otorrhœa ceased; thus the second allegation was disposed of. It was, however, argued alternately against Dr. Miller at this point that he ought to have had a bacteriological examination of swabs from the ear. But there was no proof of any practice at hospitals to take this precaution in the absence of complications. The judge held that there was at this stage nothing to cause Dr. Miller to suspect a diphtheria complication, nor did he so suspect; if, therefore, the child was discharged in an infectious condition, Dr. Miller was not to blame or legally responsible. In view of this finding, Lord Fleming held it to be unnecessary to consider whether the brother and sister became infected with diphtheria owing to contact with the original patient; as, however, the point was pressed in argument, the judge dealt with it. The subsequent bacteriological examinations of swabs from the child's ear were apparently positive in seven cases and negative in five as regards diphtheria. This indicated to the judge that the evidence was far from strong; there was, he said, no clinical history to show conclusively that the child ever suffered from diphtheria; it was not proved that the diphtheria bacilli present in the child's system were of the virulent type. "If I had to decide this question," said Lord Fleming, "I think I should be bound to hold that the pursuer had failed to prove that the diphtheria of which the sister died had been contracted by infection from Duncan." Finally he observed that not only was Dr. Miller not guilty of any negligence, but that the children had received every proper care and attention while in his hands. He added a sympathetic reference to the unhappy misfortunes of the family. Without failing in sympathy to the father of these unfortunate children, the medical profession will have some sympathy, too, for the doctor whose professional reputation was attacked. The proceedings are estimated to have cost Dr. Miller's representatives not less than £1000. As it is understood that there is scant chance of recovering this sum from the unsuccessful claimant, the case (in which the Medical and Dental Defence Union of Scotland undertook responsibility) is another instance of the importance to the medical practitioner of being adequately covered against such losses.

The Question of Law.

With regard to the broader question of law which the legal correspondent has raised, the nature of the claim is similar to that in the action of Evans against the Liverpool Corporation, tried by Mr. Justice Walton in 1906. On that occasion the alleged facts were that a boy, 6 years old, had a mild and ordinary attack of scarlet fever, that he was removed to the corporation's fever hospital for acute cases, and was passed out to the corporation's convalescent home a month later; a few days afterwards one brother, and subsequently two other brothers, developed the disease. The plaintiff said the visiting physician of the convalescent home was negligent in allowing the boy to leave while still infectious; also that the matron and nurses were negligent in examining the boy and reporting his condition. The jury found the physician was negligent, and that the damage complained of was suffered in consequence; the matron and nurses were not held negligent. The case became a leading authority on the legal responsibility of a public authority like the Corporation of Liverpool for the actions of the medical staff of its hospitals. There was also this further point. The plaintiff contended that the doctor was negligent and that the corporation was responsible for their employee's negligence. But, quite apart from any question of the relationship of master and servant, the plaintiff's counsel argued that the corporation was liable because it had a duty not to discharge a patient likely to communicate infection. There is a well-known principle of English law laid down in the text-book case of Fletcher *v.* Rylands where one landowner constructed on his property a reservoir which afterwards overflowed and damaged the property of a neighbour. The broad principle in Fletcher *v.* Rylands is that a man who keeps a dangerous thing on his property is liable if that thing escapes and causes damage elsewhere. So, in Evans *v.* the Liverpool Corporation, it was argued that the corporation had brought upon their premises a person dangerous to others and were liable if they allowed him to go outside while in a dangerous (i.e., an infectious) condition. Walton, J., came to the conclusion that there was no sufficient ground for holding that any such duty or obligation existed on that occasion.

A patient who sues a doctor for alleged negligence does not necessarily rely upon the existence of an implied contract to use adequate care and skill. Anyone who suffers from medical malpraxis is not obliged to establish privity of contract in order to recover damages. The claim can be put forward as a breach of duty as well as a breach of contract. The doctor who undertakes to treat any patient represents himself as possessing ordinary professional capacity. In the old legal phrase, *spondet peritiam*, he pledges his skill and becomes bound for the exercise of adequate professional care. If by his lack of capacity or care the patient is injured, the patient has an action against the doctor for the breach of the duty owed in this respect. The recent Scottish action, set out at length above, establishes no new principle because, fortunately, the plaintiff failed all along the line. The only point on which Dr. Miller's representatives did not succeed was an initial attempt to invoke the shelter of the Public Authorities Protection Act. That enactment, like the protecting words in Section 330 of the Lunacy Act, has scarcely been as useful to the medical profession as Parliament may be supposed to have intended.

UNITED STATES OF AMERICA.

(FROM AN OCCASIONAL CORRESPONDENT.)

The Sale of Wine Tonics.

THE free sale in drug stores of tonics containing and largely consisting of wine has been a large source of leakage of potable alcohol through the legal sieve of prohibition. Apparently some attempt is to be made to dry up this source and apparently the medical profession will not lend much support to the attempt. The indications are found in a letter to *California and Western Medicine* (December, 1929, xxxi., 445) and in editorial comment thereon. The correspondent encloses a copy of an ordinance recently passed by the city council of Los Angeles prohibiting the sale of wine tonics, defined as "any tonic or any medicinal preparation containing one-half of 1 per cent. or more of alcohol by volume, which is capable of being used as a beverage." The penalty prescribed is $500 for each sale or six months' imprisonment or both. No exemption is made for prescriptions of any kind. The ordinance was passed over protests from the pharmaceutical and medical professions. The mayor signed it after it had been pointed out to him that the definition of wine tonic was such as to include a number of common prescriptions. Several other cities in the State of California are said to be preparing ordinances modelled on that of Los Angeles. Says the editorial writer: "It must be self-evident to any person of reasonable knowledge of the world that an ordinance such as this . . . will not be literally and impartially enforced. This is the kind of law-making which does much to lower the respect of many citizens for all law." It is possible that a referendum will be demanded in which case the ordinance will lie over until election time in the autumn of 1930.

Enforcement of Prohibition.

The report of the prohibition commissioner for the last fiscal year records 66,878 arrests and 55,546 convictions, including 19,074 jail sentences. The aggregate of these sentences amounts to 7443 years' imprisonment. Fines totalling more than $7,000,000 were imposed by the courts. More than 7000 automobiles valued at nearly $3,000,000 were confiscated. Senator Borah has recently attacked the administration on the ineffectiveness of prohibition enforcement. After his speech in the Senate he visited President Hoover, who is said to be contemplating measures for increasing the severity of enforcement.

Infectious Disease.

The report of the Public Health Service now published covers the calendar year 1928. The high incidence of small-pox is maintained. Deaths from pellagra are increasing despite our new knowledge of the ætiology of this disease. The deaths from this cause in 1928 were 6652 as compared with 4794 in 1926. Reported cases of tularæmia were 480 with eight deaths; but that many cases must have gone unreported. The tuberculosis death-rate of 77·5 per 100,000 is the lowest on record in this country. Low records were also made for typhoid fever and for diphtheria. Brill's disease was prevalent especially in the South-Eastern States; 143 cases were reported and 12 deaths. The Department of Commerce reports a general death-rate of 12 per 1000 as compared with a rate of 11·4 in 1927. The greatest increase was shown in deaths from heart disease. Controlled statistics on the efficacy of toxin-antitoxin administration are available in the report of the Detroit Department of Health. There are in the city 153,000 children under 11 years of age who have been immunised, and 142,800 who are still unprotected. There have been no cases of diphtheria among the former group but 1805 cases with 222 deaths among the latter. The city health department has a list of over 800 physicians who will give toxin-antitoxin at stated hours, charging $1.50 per injection to those who can pay and nothing to those who cannot.

Health and Scholarship.

The relationship between health and scholastic attainment has been investigated at the University of Minnesota. Records were made of physical defects, habits of living, and social and economic status of 141 university students who were on probation because of poor scholarship. Corresponding observations were made on 496 students who were doing satisfactory work and who came voluntarily for health examination. The same physicians made both sets of observations and the statistical results were then analysed, the chi square test of independence being used to compute the possibility of a chance difference equal to or greater than the observed difference between the two groups. The probation group showed an excess of some physical defects that was almost certainly significant. There were: defective hearing of extreme grade, overweight, flabby musculature, and anæmia. Other factors associated with poor scholarship were found to be: student completely self-supporting; employment at physical or clerical work during the summer vacation; student considers himself particularly self-conscious; student gives four or more affirmative replies relative to the emotional make-up of the individual.

An Ape Farm in Florida.

A gift from the Rockefeller Foundation has made possible the acquisition by Yale University of an ape farm in Florida. The farm will include a special laboratory for psychobiological research and will at the same time be a source of supply of anthropoid apes for the laboratory in New Haven. It will be under the general direction of Prof. Robert M. Yerkes, who began the work on comparative psychobiology at Yale five years ago. The headquarters of research will remain at Yale and will be associated with the new Institute of Human Relations, but senior members of the staff will make frequent visits of some months' duration to the station in Florida. Observational field camps are also to be established in Africa and Malaya where the anthropoids and other primates will be studied in their natural environment.

Professional Advertisement.

Some interest has been aroused by the recent suggestion of the editor of the *Bulletin of the Chicago Medical Society* that the medical profession should use the advertisement columns of the daily papers for making known the economic and scientific problems with which they are faced. This is hailed in some quarters as a withdrawal from their traditional position. As a matter of fact, it is not at all a novel suggestion in this country. Advertising by medical societies in the lay press has already been practised in many parts of the country. It may serve not only to put the views of the local medical group in regard to social medicine but also, and perhaps better, to educate the public in regard to the possibilities of preventive medicine. Many medical men feel a quite natural reluctance to urge upon their patients such measures as the periodic health examination or the use of toxin-antitoxin knowing that they must charge a fee for such services if they are accepted. At the same time the satisfaction of doing preventive work and the consciousness of its importance make it hard to keep entirely silent and to wait for all initiative from the public. Group advertising provides the remedy.

SCOTLAND.

(FROM OUR OWN CORRESPONDENTS.)

The Edinburgh Royal Infirmary Appeal.

AT the annual meeting Lord Provost Whitson intimated that the appeal will be launched this summer. The Royal Infirmary, which boasts of never having refused an emergency case, completed its 200 years of service last year. The initiative in founding the infirmary was taken by the Royal College of Physicians, and it has developed into a splendid centre in which the Royal Colleges play a greater part than ever. Its growth is one of the romances of medicine. Last year there was a slight falling off in the ordinary income, but there was a considerable increase in the extraordinary income. While the ordinary annual income is in the region of £115,000, extraordinary income totalled nearly £140,000 last year, and there need be little fear for an institution so deeply rooted in the community. No doubt the waiting-list is still considerable, but the efforts to meet it are commensurate. The Regional Hospital Committee for the South-East of Scotland including Fife is considering the developments of the immediate future. The Edinburgh Town Council and other local authorities in the area must submit their schemes to the Department of Health before the end of March. When all these are collated and analysed we shall have the beginning of a regional hospital organisation. Misgivings in the minds of those in charge of the smaller hospitals arise mainly from the novelty of the programme; as the facts are more closely scrutinised the difficulties of adjustment will disappear. Meanwhile the infirmary is contemplating an appeal to the general public in order that the extensions over the Watson School site may proceed. It is understood that these extensions will include obstetrical and gynæcological wards, but the pressure from the public demand, both urban and rural, continues high, and it is possible that these extensions may not be adequate. There can, however, be no doubt that the South of Scotland will make the same handsome response as the North-East has done in the last three or four years to the Aberdeen appeal.

Delay in Rendering Accounts.

A claim of over £200 by a medical practitioner for professional fees has lately been dismissed in the Scottish courts. The patient died two years ago at the age of 78, and the claim covered services rendered over a period of 16 years. His executors contended that he was throughout this period a panel patient. At first, they said, the doctor treated him along with the rest of his fellow-workmen under an arrangement by which the employers accepted responsibility for the cost of treatment. Later he was an ordinary panel patient, and for the final eight years (after reaching the age of 70) he remained entitled to medical benefit without further contribution. These contentions being issues of fact accepted as established before the court of first instance, there is no more to say of them unless in the event of an appeal. No doubt there were special reasons for the delay in pressing the claim; there is no need to emphasise the disadvantage of allowing an account to run too long. A judge instinctively dislikes stale claims; the law itself has no tenderness for them. In England the Statute of Limitations peremptorily draws the line at six years unless the debtor has kept his liability alive by some form of acknowledgment or part payment. Patients themselves would be more than human if gratitude for professional services did not diminish as the past recedes in the memory. The medical profession has perhaps a special duty to be businesslike in the rendering of accounts, for by custom the patient leaves to the doctor the task of deciding what fee is reasonable and of keeping a record of visits and details of treatment. Indeed on the rare occasions when the items of the doctor's bill are challenged as excessive, it is usually because the account has been allowed to run so long that the final total surprises by its magnitude.

Greenock Auxiliary Hospital.

Greenock, a town of over 80,000 inhabitants, has added to its resources by opening at Larkfield an auxiliary hospital which cost £60,000 to build. The hospital has two wards of ten beds each for convalescent patients from Greenock Royal Infirmary. It has also —and Sir Donald McAlister commented on the importance of this—a wing of rooms with accommodation for 20 paying patients. The new hospital is situated on the north slope of the Inverkip valley in a very picturesque situation. Mr. Matthew Rankin and his sister had offered £20,000 on condition that the work was commenced within a year. Greenock is an extremely busy ship-building and shipping centre, as well as the examining station for the Clyde Port Sanitary Authority

---

BETHNAL GREEN POOR-LAW HOSPITAL.—Lord Monk Bretton, Chairman of the London County Council, last week opened a new operating theatre suite which has been provided at this hospital by the guardians at a cost of £7000. The theatre contains a gallery from which probationer nurses can watch the operations through a glass screen; a shower-bath has been provided for the surgeons. The old theatre had become unsuitable for the performance of nearly 1000 operations a year.

NEW DELHI HOSPITAL.—On Friday last the Viceroy of India, Lord Irwin, laid the foundation-stone of the new general hospital for New and Old Delhi. When completed the institution, which is to cost £562,000, will contain 364 beds; the first portion, to be ready in two years, will provide 254 beds. In his speech the Viceroy said that the hospital appeared to be condemned—by reason of the reluctance of Indian women to become nurses—to open with an insufficient nursing staff, and he appealed to them to contribute more of their number to the nursing profession.

"Audi alteram partem."

COMPULSORY TREATMENT OF VENEREAL DISEASE: A PROTEST.

To the Editor of THE LANCET.

SIR,—The question of the compulsory treatment of venereal disease is again being raised. A conference of representatives of local authorities, held under the auspices of the British Social Hygiene Council in Glasgow on Oct. 18th, 1929, passed a unanimous resolution urging the Corporations of Edinburgh and Glasgow to continue their efforts to obtain from Parliament additional powers for the control and treatment of persons suffering from venereal disease. In the late Parliament Bills in favour of compulsory treatment were thrown out, and the reports of the principal officer show that the Ministry of Health may again oppose such legislation. It seems incredible that the advisers of the Scottish corporations should have kept them in ignorance of the important facts which have recently been added to our knowledge and which show that Parliament took the right line.

It is obvious that the V.D. campaign is not the success which was anticipated, although more people present themselves for diagnosis, no less than 34 per cent. being found on examination *not* to be suffering from venereal disease. There has been a decline in the number of patients suffering from syphilis since 1920, the peak year, but a careful examination of records from clinics in different countries shows that the curve of fall, 1920–1926, is suspiciously like the decline curve of many kinds of epidemic, and may, therefore, have no relation to treatment. Moreover, it is reported from many quarters that there has been a slight increase since 1926, although there has been no abatement, but rather an increase in the amount of treatment.

Even in 1913, the year of the International Congress in London, which might be called the apotheosis of salvarsan, the idea of a *therapia magna sterilisans* was already shaken, for combined arsenic and mercury treatment was advocated. It soon became evident that the intravenous injections were of greater immediate danger to the patient than syphilis itself, and those who had experience of mass salvarsan therapy during the war will remember that many lives were lost thereby. To avoid the grave nervous complications, and the damage to the liver and skin, it became necessary to weaken the drug and to give smaller and smaller doses. Standard courses such as are described in the recent report published by the Medical Research Council[3] consist of at least 20 doses of "914" (with either bismuth or mercury) for a sero-negative primary case, and 30 or more in a sero-positive primary, and so on, in rapidly increasing ratio.

Now, Klauder[1] has shown that repeated small doses of arsenical compounds may produce in animals arsenic-resistant spironemes, and there is good reason to believe that this obtains in man. A leading London syphilologist writing to me recently stated that he was certain that the cases of syphilis seen to-day were more refractory to treatment than those seen ten years ago. Long ago Finger pointed out the risk of converting a disease which was mainly an affection of the skin and mucous membranes into one in which the heart and great vessels and central nervous system were involved. Prof. Sarbó,[2] of Budapest, has observed that the incubation period of general paralysis has been shortened and suggests that under the influence of treatment the life-history of the spironeme is changed, and that the organisms hide up in the adventitia of the vessels and in the organs, and there multiply when the resistance of the host weakens. Even Colonel Harrison,[3] so long an advocate of repeated injections, now says: "It may be that in giving a long series of injections we may be damaging a very necessary ally in the shape of the tissues." In fact, he has now reverted to larger spaced doses, on a principle followed by Drake and Thompson[4] at King's College Hospital for many years.

The most disquieting evidence yet produced is that of Prof. A. Warthin,[5] who, at Manchester, gave the results of a large number of post-mortems on syphilitics, who had had prolonged arsenobenzol treatment, and stated that he had seen *no single case of cured* syphilis. Most of the organs and the great vessels and heart showed active disease. Langer[6] reports an enormous increase in aortic disease from 33 per cent. in 1907 (before salvarsan) to 63 per cent. in 1915, and 83 per cent. in 1925. These observations are confirmed by Bergel and Rosenthal's[7] statistics from 70,000 autopsies. There is also evidence of uneasiness in the minds of neurologists as to the increase of general paralysis and tabes.[8] [9]

On the other hand, the remarkable papers of Bruusgaard[10] and his Norwegian colleagues demand our earnest study. Here we have a careful follow-up, over many years, of a large number of patients who had been under the care of the great Cesar Boeck. Boeck held that syphilis produced its own immunity, and that the so-called specific remedies merely removed symptoms. His patients were, therefore, practically untreated. Yet the incidence of G.P.I. in Bruusgaard's long series was only 0·6 per cent. The full significance of these observations, both on the nervous system and the great vessels, must be studied in the original. In this connexion it is worthy of notice that African races, suffering from widespread syphilis, rarely show either G.P.I. or tabes, and they are almost untreated. It cannot be a different strain of spironeme for grave nervous symptoms are seen in Europeans who contract the disease from the native. Fierlinger,[11] in the League of Nations Report, doubts whether there is a real decrease in the incidence of syphilis, and whether the treatment has the value claimed for it, and states that inquiries on a large scale are being made, and hopes to have an analysis of 50,000 cases by the end of the year.

It is to be hoped that somebody will make an inquiry on Bruusgaard's lines, and it would appear to be a form of research worthy of the attention of the Medical Research Council. The investigators must obviously be independent of the clinics, and there must be an authoritative statistician. The recent report of the M.R.C. is on quite different lines and valueless for the proposed inquiry.

Lastly, I recall that just as Boeck believed in the self-cure of syphilis, my old teacher, Sir Jonathan Hutchinson, taught forty years ago that "time as well as mercury cured syphilis." Leading homœopaths have told me the same; and now, I note, that Dr. Osmond of St. Thomas's has made the same discovery, for he says "to establish a cure, time is just as important as a negative Wassermann."

I trust, therefore, that the advisers of the Scottish Corporations will restrain the worthy baillies from pressing for penal legislation, for a very good case could be made for "conscientious objection" to prolonged treatment on present lines.

I apologise for this long intrusion on your space, and hope that some competent authority may take up the question of gonorrhœa.

I am, Sir, yours faithfully,

JAMES H. SEQUEIRA, M.D., F.R.C.P. Lond.,
F.R.C.S. Eng.,

Consulting Physician to Skin Dept., London Hospital; late a Member of Lord Trevethin's Committee, and Chairman, Society for Prevention of Venereal Diseases.

Kenya Colony, B.E.A.

INFECTIVE TONSILS AND RHEUMATISM.

To the Editor of THE LANCET.

SIR,—In their very interesting study of rheumatic disease in children, published in THE LANCET of Jan. 11th, Dr. Campbell and Dr. Warner have scarcely justified their conclusion that "complete enucleation of the tonsils is without effect in preventing the onset of rheumatism." In their Table XV. they show that the incidence of rheumatism, subsequent to tonsillectomy, in completely tonsillectomised children is the same as in non-tonsillectomised children, and that in incompletely tonsillectomised children the subsequent incidence of rheumatism is double that in either of the other two classes. Now it may be presumed that tonsillectomy, whether complete or incomplete, is performed because the tonsils are diseased, and therefore that all the children who had a tonsillar operation had diseased tonsils. Incomplete removal of diseased tonsils is tantamount to doing nothing, for the focus of infection still remains. On the showing of the authors, in their series of children with diseased tonsils, the incidence of rheumatism following incomplete tonsillectomy was double that following complete tonsillectomy. It is difficult to escape the conclusion that, in the series of cases quoted, complete tonsillectomy did reduce the incidence of rheumatism.

I am, Sir, yours faithfully,
WILLIAM W. KAY.

Medical School, The University, Manchester, Jan. 11th, 1930.

GASTRIC DEFECT IN PERNICIOUS ANÆMIA.

To the Editor of THE LANCET.

SIR,—In an interesting annotation last week (p. 92) on the Effect of Liver on Nervous Lesions of Pernicious Anæmia, you say

> "there can be no doubt of the persistence of achylia gastrica under liver treatment, and it certainly seems as though liver therapy was largely symptomatic and not directed towards the actual cause in this disease. . . . Truly radical therapy is likely to take the form of eradication of some provocative toxin . . . rather than the removal of symptoms by the use of liver."

The fact that achlorhydria persists while the patient under liver treatment maintains excellent health appears to me to point in a very different direction—namely, that achlorhydria plays no important part in the pathogenesis of pernicious anæmia and subacute combined degeneration. The discovery of achlorhydria in these two conditions was an enormous diagnostic advance, but it advanced treatment not at all. The administration of hydrochloric acid to these patients in the last ten years has produced no demonstrable result.

I was surprised that in this article no reference was made to the interesting and relevant experiments of Castle and Townsend which were fully reviewed in a leading article in your columns three months ago. (1929, ii., 829.) These experiments went to prove that the cause of pernicious anæmia was a gastric defect which resulted in the absence of a "principle" (formed by an enzyme action of the normal gastric juice on protein) necessary for the prevention of pernicious anæmia; this principle being elaborated in every normal stomach, and even, presumably, in those many stomachs which have achlorhydria, and whose possessors do not develop pernicious anæmia. These experiments suggest to me (though not apparently to the authors) that while the gastric defect and the absence of enzymes are all-important the achlorhydria itself may play no part in the development of the disease; in which case the achlorhydria is but a side issue—a natural consequence of the gastric defect.

This uncertainty as to the influence of achlorhydria on the pathogenesis of pernicious anæmia is an excellent illustration of the problems which the biochemist is setting (or the pits he is digging) for the clinician by the multiplication of chemico-physical analyses of body fluids. *An alteration in blood-calcium, blood-cholesterol, blood-sugar, blood-urea,* hydrogen-ion concentration, sedimentation velocities and (save the mark) the hydration of protein particles, all propound the same question. Is it a link in the causative chain of a disease or a by-product of the morbid process? This is a problem that may occupy the physician and the biochemist for a century.

Your annotator appears to agree with D. McAlpine[1] that the evidence is against the improvement or retardation of subacute combined degeneration under liver treatment. If this is so, and the theory of Castle and Townsend is accepted, it is certain that the cause of the gastric defect in pernicious anæmia and the toxin which poisons the nerve parenchyma are identical—that is to say, the alteration in gastric secretion has no part in the development of the nervous lesions. In this case it seems to me illogical for McAlpine to insist as strongly as he does on the necessity for the administration of hydrochloric acid to these patients with subacute combined degeneration. Your annotator appears to speak somewhat disparagingly of the "removal of symptoms by the use of liver," but I regard it as *first-rate substitution-therapy* strictly comparable to use of insulin in diabetes. It is likely to be a long time before we are able to prevent the poisoning of the enzyme-secreting cells in the stomach or the exhaustion of the beta-cells in the islands of Langerhans. Until that day of "truly radical therapy" dawns we shall have to be content with symptomatic treatment such as liver and insulin.—I am, Sir, yours faithfully,

Derby, Jan. 12th, 1930. DOUGLAS HUBBLE.

EMPHYSEMA TREATED BY MECHANO-THERAPY.

To the Editor of THE LANCET.

SIR,—I confess that I am amazed at Dr. Kellgren-Cyriax's contention that the barrel-shaped emphysematous chest can be made permanently smaller—and to a substantial degree—by mechanical means, and that such reduction in size is capable of benefiting the patient. Further, I cannot but think that the doctor is carried away by her enthusiasm (a useful asset in its way, though sometimes dangerously misleading), in claiming to be able to restore, "in greater or less degree," the loss of pulmonary elasticity characteristic of hypertrophous emphysema, and that she is as little likely to achieve success in this as in an attempt to restore the unwelcome tell-tale loss of cutaneous elasticity (with its accompanying wrinkles) which so obstinately progresses with the flight of time.

I would remind Dr. Kellgren-Cyriax that I did not in my letter suggest that any harm would result from properly devised expiratory exercises in hypertrophous emphysema, nor that fatal asphyxia would result from them: my point was that the enlarged thorax of emphysema is compensatory, and that if the thorax of a patient, suffering from advanced hypertrophous emphysema, were reduced to the dimensions normal to that person in early adult life, he would effectually be asphyxiated.

Seeing that Dr. Kellgren-Cyriax has the opportunity of treating many cases of advanced hypertrophous emphysema, may I suggest a line of valuable clinical investigation? Let careful measurements and circumferential tracings of the chest be made before and after treatment of ten successive cases of the barrel-shaped emphysematous chest, these measurements and tracings to be taken by an independent, skilled observer, who shall not know whether the patients have undergone special treatment. In order to ensure accuracy, the weight of the patient should be taken before and after treatment, and a note of the amount of adipose tissue enveloping the bony thorax. I am, Sir, yours faithfully,

---

MEDICAL FOUNDATIONS:

A RENEWED PLEA TO TESTATORS.

To the Editor of THE LANCET.

SIR,—About a year ago you allowed me to publish in your columns a plea that those members of the profession who are without dependents, or have more than sufficient to provide for their dependents, should be urged when disposing of their property by will to consider the claims of the two great professional charities, the Royal Medical Foundation of Epsom College and the Royal Medical Benevolent Fund.

From certain private correspondence which ensued I have reason to believe that this plea may in time bear some fruit; but it has by no means gained sufficient acceptance, to my mind, and I ask your permission to reiterate it. Only last week the press contained particulars of the will of a Doctor of Medicine who left over £100,000 for distribution between ten charities; had he added the two I have mentioned to the list, he would have solved many difficulties for their councils, which are seriously hampered for lack of funds. Another member of our profession left £10,000 last year to charity: half to a hospital, and half to the Lifeboat Institution, if I remember rightly. Yet another left a large sum, about £50,000 I believe, to an educative foundation in the North.

There are few of us who can ever hope to distribute money to charity on this scale. But those few can do so much for their professional colleagues, through the two great medical charities, that they may surely be urged to recognise a duty in this matter superior to other claims, even when the latter include such excellent institutions as hospitals, universities, and lifeboats. I am, Sir, yours faithfully,

HENRY ROBINSON.

16, Bramham-gardens, S.W., Jan. 12th, 1930.

TREATMENT OF THE TYPHOID FEVERS.

To the Editor of THE LANCET.

SIR,—I would venture to comment on certain statements in Dr. A. E. Gow's very instructive articles in your issues of Jan. 4th and 11th. My experience of typhoid dates from the Boer War, when for a year I had charge of 90 enteric beds which were always full, convalescents being transferred at an early stage to other lines. My mortality of 30 compared favourably with that of others and to that extent supports the principles of treatment which I adopted. Dr. Gow recommends three pints of milk with additions; I consider the typical enteric stool to be the product of three pints of milk imperfectly digested. I gave a maximum of one pint of milk, supplemented by raw meat juice and white of egg with lemon juice. The chief danger of enteric is from distension and its complications; imperfect digestion is therefore very dangerous. I question whether enteric patients should not, like babies, be fed three-hourly instead of two-hourly.

I should like to see all enemas given by means of a douche can with a No. 12 catheter on its nozzle, and I have never found soap-and-water enemas with an ounce of turpentine do any harm. Talking of drug treatment, my 90 beds being arranged in rows of 30, I tried various things and found a quarter of a grain of calomel six-hourly useful in disinfecting the intestinal contents and keeping the actions regular, and I soon adopted it for all my patients. I avoided carbolic derivatives as likely to favour distension. I believe in the wet pack, one ply of sheet under a blanket laid over it. The last thing desired is to produce a sensation of cold and consequent constriction of superficial vessels. One imitates Nature by putting on a sheet wrung out of water, which feels warm to the patient and is kept wet by sponging from time to time as evaporation takes place. Four ply of sheet is half-way towards the hot pack, with the initial disadvantage of possible shock constriction from cold. Cradling at a temperature of 103° F. (speaking now as a patient) is a most uncomfortable process, while the evaporating pack is more efficacious.

On my diet I saw no cases of thrombophlebitis. It may be I produced a calcium deficiency, or that three pints of milk produce a calcium excess—my three-pint colleagues had many cases of thrombosis. I used to get cases of painful toes lasting about ten days, and these began in convalescence; perhaps the increased diet of that period caused them. I am sorry to see the statement that alcohol hardens the skin. Alcohol is serviceable as a disinfectant and to dry the skin; the really important thing the nurse does is to massage the bony areas with a smooth soapy hand, thereby maintaining the local circulation. Speaking again as a patient a bath towel made into a ring pad gives a greater sense of support than does an air cushion. A water bed gives a sense of insecurity.

I am, Sir, yours faithfully,

R. W. JAMESON.

West Wickham, Kent, Jan. 13th, 1930.

ZONDEK AND ASCHHEIM TEST FOR PREGNANCY.

To the Editor of THE LANCET.

SIR,—Further confirmation as to the practical value of the Zondek and Aschheim test for pregnancy, as described by H. Allan and F. Dickens in your issue of Jan. 4th (p. 39), is given by F. Wermbter and E. Schulze, of Berlin, in a paper published in the *Klinische Wochenschrift* (1929, viii., 970). In all their cases the presence of a hormone, held to be anterior pituitary, was demonstrated by characteristic macroscopic changes in the mouse: alteration in the œstrus (anterior pituitary reaction I.), petechiæ in the ovaries (anterior pituitary reaction II.), and corpora lutea atretica (anterior pituitary reaction III.). A brief résumé of their findings is as follows:—

—	Number.	Negative.	Positive.
Normal pregnancy.			
Fifth to sixth week ..	18 } 51	— } 1	18 } 50
Seventh to eighth week ..	16	—	16
Third to tenth month ..	17	1	16
Interrupted pregnancy.			
Fœtus died..	2	—	2
Threatened abortion cured	1	—	1
Extra-uterine gestation ..	4	1	3
Puerperium.			
After normal birth ..	1	1	—
After extra-uterine gestation	1	1	—
After or during abortion..	9	7	2
No pregnancy.			
Amenorrhœa	8	8	—
Retroflexion of uterus, adnexitis	32	31	1

Total: 109 cases, including 2 failures.

Thus, out of 51 normal pregnancies, 50 gave a positive reaction, among which 18 were between the fifth and sixth week. In one woman the urine gave a negative reaction on the thirty-fourth and the fortieth day of pregnancy, but was positive on the forty-sixth. Of the 17 cases in the third to the tenth month, the negative reaction occurred in the ninth month, one week before the birth of a living child—a failure of no practical significance. The negative reaction in one of the four cases of extra-uterine reaction gestation occurred where bleeding had been in progress for five weeks, and operation subsequently revealed a hæmatocele.

In 40 non-pregnant patients tested, the reaction only failed once; where a left-sided inflammatory adnexal tumour was present—in all probability an extra-uterine pregnancy.

I am, Sir, yours faithfully,
GEORGE H. MORRISON, M.B., Ch.B. Edin.
London, S.W., Jan. 8th, 1930.

PROGRESS IN UROLOGY.

To the Editor of THE LANCET.

SIR,—If Mr. Morson reads my paper carefully he will see that I was referring particularly to the work done in Dr. Young's clinic at Baltimore. He will also see that I did not confine my remarks to emanation seeds, but included radium element in small needles. It was not possible in a short account to give details, but the method of treatment under discussion does not entail the retention of the emanation seeds, which are provided with short threads by means of which they can be removed when they have served their purpose. The production of a vesico-vaginal fistula must surely be due to involvement of the vaginal wall by the growth or faulty application of the radium. The good results obtained by Young and his co-workers are there for all to see who have time and inclination to visit his clinic.

I am, Sir, yours faithfully,
Belfast, Jan. 13th, 1930. ANDREW FULLERTON.

COMPLICATIONS OF OPERATIONS FOR PILES.

To the Editor of THE LANCET.

SIR,—In reply to Mr. Morley's letter in your issue of Jan. 4th (p. 53) regarding the report of the last meeting of the Subsection of Proctology of the Royal Society of Medicine, it is true, I believe, that I was the only speaker who referred to the injection method, but Mr. Morley should realise that the subject of Complications of Operations for Piles had been arranged for the discussion, and it was hardly the place therefore for labouring the merits of the injection treatment. I quite agree with the contention that uncomplicated internal piles can be cured by injection, and I am an enthusiastic believer in ambulatory treatment of many rectal conditions. There is, however, a certain small proportion of pile cases that has to submit to operation—namely, the enormous prolapsing piles, fibrous internal piles or piles complicated by the presence of a deep fissure, large external piles or some other lesion. The subject in question, therefore, was a very proper one for a discussion, even though the report has provided Mr. Morley with "a text for the advocates of injection."

Mr. Morley's benevolent welcome of me as a convert to the injection method is somewhat overdue seeing that I have been practising and teaching this method for the last ten years. The teaching has not been in writing, however, but practical clinical teaching carried out regularly at St. Mark's Hospital to post-graduates from all parts of the world. The out-patient clinics at St. Mark's Hospital provide, I venture to say, a wealth of clinical material in rectal work that is unsurpassed in this country, and for many months now I have used the 5 per cent. solution of phenol in vegetable oil by the method of Albright and Blanchard of which Mr. Morley is himself a follower. The results have been so good that I have to recommend operation now in only a very small proportion of the total number of pile cases seen.

As regards Mr. Morley's criticism of the syringe and needle which I have recently described, I must confess that I am not impressed by his unfavourable view of it. In his original article (THE LANCET, 1928, i., 543) Mr. Morley advocates injection of "a large quantity (some 1 to 3 c.cm.)," and in his work entitled "Hæmorrhoids," fourth edition, 1929, he is still more modest, saying (p. 107), "it will usually be found that each pile requires from ½ to 1¼ c.cm. of the oil to produce the requisite degree of distension." Again, the needle which Mr. Morley has described and advocated is only 4¾ in. long, which, when used with a larger syringe, gives very little more effective length than the one I have suggested. Therefore I regard his latest pronouncement of 10 c.cm. dosage per puncture and a 7 in. needle as a straining for a dramatic effect which bears little relation to everyday work. It is the man behind the syringe that counts, and one syringe and needle may be as good as another.

Mr. Morley may be glad to learn that I still have a couple of his needles in routine use at St. Mark's. The syringe that I have described is effective in practice and enables one to inject the solution sufficiently high and in adequate amounts. I have had no need to inject more than 3 c.cm. per puncture, and the syringe is easily refilled when more than a total of 3 c.cm. is required for any particular case. The bayonet fitting for the needle and its wide bore are the essential points which can obviously be adapted, if required, to larger syringes and to needles of any conceivable length and shape.

I am, Sir, yours faithfully,
London, W., Jan. 13th, 1930. W. B. GABRIEL.

THE BRUIT D'AIRAIN.

To the Editor of THE LANCET.

SIR,—Questions of meaning and translation are always interesting, but their solution has a methodological importance. The best way to set about it seems to be to work back from the words to the notions symbolised, and then to the "things" thought about. Now, if Dr. McLaughlin really wishes to cross swords with "Anglo-Gallicus," and *glaives d'airain* are nominated by their seconds, the weapons produced at the *triste rendezvous* in Hyde Park will certainly be Bronze Age relics, made of the predominantly copper and tin alloy that we call bronze nowadays—it was not always called thus, in England. Swords made of the copper and zinc alloy which alone is now called brass will not serve their turn. On the other hand, it is possible that they may be dissuaded from their fell purpose on listening to the harmonious *tintement* from the Lansbury Tower. I say this, because I am told that each bell (or, as a poetical Frenchman might say, *chaque airain*) has been cast in this copper and tin alloy we call bronze. If I am wrong, and these bells are really cast in brass, then, of course, the discord on the grass will be aggravated by the jangling in the air. And the whole evening will end on a "brassy note" very unlike that of any pneumothorax I have ever percussed. But I subscribe myself, very hopefully yours,
Jan. 11th, 1930. GALLO-BRITANNICUS.

To the Editor of THE LANCET.

SIR,—"Anglo-Gallicus" tells us that the name of Laennec should be spelt thus, without vowel-ligature or diæresis, just as are the place-names Caen, Laon, and the like. So the owner of the name wrote it, and so it appears on his statue in his native place of Quimper, Lower Brittany. But it has been the practice for 80 years or more at all events to place two dots over the third letter in order, no doubt, to acquaint the non-gallic reader how the name should be pronounced, and the practice is now so deeply ingrained that it may be well to continue it. Laënnec on this view is the anglicised form of Laennec. "Anglo-Gallicus" does not seem to be aware that Laennec is trisyllabic, whereas Caen and Laon are monosyllabic; current French dictionaries of proper names are quite clear on this. My own copy of Larousse Classique Illustré not only indicates the trisyllabic pronunciation of the name, but puts a diæresis over the first e to ensure it.

I am, Sir, yours faithfully,

Jan. 11th, 1930. BOBO.

LIABILITY TO DAMAGES FOR INFECTION.

To the Editor of THE LANCET.

SIR,—Actions of damages against a medical man are not infrequent nowadays, but a recent decision of the Scots courts seems to break new ground (Carmichael *v.* Miller's Exrs., Dec. 26th, 1929). A paterfamilias claimed £600 from the doctor in charge of the local hospital for causing the death of his daughter by negligently discharging his son while suffering from diphtheria. It was said that there had been carelessness, firstly in failing to recognise a certain development in the course of scarlet fever as incipient diphtheria, and also in any event in sending home a child with an infectious discharge from the ear. The defender was successful on both issues, for the judge held that he had no reason to diagnose diphtheria or to suspect danger from the ear condition. But though he escaped on the facts important legal questions were assumed against him.

It seems never to have been decided hitherto that a medical man was liable to be sued by any third party who might be indirectly affected by his actions. It was always obvious, of course, that he was morally bound to guard the general public against infection, but the existence of a legal duty is a different matter. One might naturally think that his only legal obligation was to his patient or to the person who employed him. This case did not, of course, depend in any way on the tie of blood between the members of the family affected. If a sister has a claim, so has any stranger. The only difference is a practical one that it would be much harder for him to prove the exact source of his infection. It was a pure accident also that it was a relative of both who sued, for the father was a mere figurehead to enable his infant daughter to appear in the Law Courts. The result of it all is that if a doctor by some oversight allows an infected patient to come in contact with others he may be liable in damages to an almost unlimited extent. This is surely a new and startling proposition.

Even without this added burden one must remember that the medical practitioner is badly handicapped in contrast with other professional men. Lawyers, architects, and so forth are not liable to anyone except the person who employs them, because the law does not recognise any duty apart from contract. If a father calls in a solicitor to make his will a child has no redress should his name be carelessly omitted. But if a surgeon sews up a sponge inside him things are quite different. The reason for this unfair distinction is that the law regards physical injury much more jealously than monetary loss. Medical men are thus penalised by the accident that their actions affect persons rather than pockets. The real remedy is, perhaps, not to reduce the liability of doctors but to impose the same standard on other professions.

If the new idea catches on, a rich vein of damages may be opened to a certain section of the legal fraternity. Defenders, however, will always have the advantage as regards the facts. It is, as a rule, difficult to prove that infection has been incurred from any particular source. In this case the difficulty was all but surmounted by special circumstances, and the proof only broke down because no virulent bacilli had been detected in the ear. The family were all young, lived in a small town in the Highlands, and were much at home. Another child also took diphtheria, and no other cause could be suggested, the evidence as to the drains being negative. This was unfortunate, as it may result in future claimants underestimating the obstacles to be surmounted, and in medical men being forced to incur considerable legal costs. One can only hope that these actions will not become as common as those directed against physicians who have reluctantly performed the odious duty of certifying a person as insane.

I am, Sir, yours faithfully,

Jan. 11th, 1930. LEX.

PSITTACOSIS.

To the Editor of THE LANCET.

SIR,—An investigation on psittacosis is at present being carried out at the London Hospital and I should be grateful if any doctor who has had to deal recently with a case of the disease would communicate with me. I should also be glad if any parrot suspected of conveying the disease could be sent to Dr. Western, Bacteriological Department, London Hospital, E. 1.

I am, Sir, yours faithfully,

ROBERT HUTCHISON.

Devonshire-place, W., Jan. 14th, 1930.

Obituary.

JAMES HOGG MARTIN, M.D., F.R.F.P.S.GLASG.,

PROFESSOR OF MIDWIFERY AND GYNÆCOLOGY, ANDERSON COLLEGE, GLASGOW.

THE death on Jan. 1st of Prof. James Hogg Martin startled a wide circle of friends and patients, for only his most intimate associates were aware of the serious nature of his illness, and they had the hope that, though there might be little prospect of his taking part again in professional life, he might yet enjoy a period of moderate health.

To Prof. Archibald Young, an intimate friend of the late Prof. Martin, we owe the following estimate of the man and his work: "Martin was in many ways a remarkable man—" he writes, from a knowledge extending as far back as their school-days, when they were both pupils of the Glasgow High School, and members of the same form. "He was one of a large family of boys and girls. His older brother and his next younger brother, also high school boys, went direct from school to college, both graduating in medicine with distinction. The older has been for a number of years visiting surgeon to the Cardiff Infirmary; the younger's professional career has also been laid in Cardiff. James, on the other hand, went into business for some years after leaving school, but when already 30 years of age, he also became a student of medicine, graduating in medicine at Glasgow University in 1907. During his student days he began to take part in teaching, acting for two years as a student demonstrator in anatomy

DR. MARTIN.

Notes, Comments, and Abstracts.

CARDIAC INSUFFICIENCY:

THE PRECURSOR OF CARDIAC FAILURE.*

BY G. J. LANGLEY, M.B.E., M.D., M.R.C.P. LOND.,
PHYSICIAN TO ANCOATS HOSPITAL, MANCHESTER, AND TO THE SALFORD ROYAL HOSPITAL.

CARDIAC insufficiency in everyday life probably amounts to shortness of breath or some precordial distress on effort, and is essentially a relative matter. We can all reach such a stage of cardiac insufficiency by over-exertion—e.g., running a half-mile race. In the first place, therefore, we must determine how much effort is required to induce such symptoms. The child can rush and tear about all day long and feel none the worse, while the aged puff and blow on very slight effort. In fact, cardiac sufficiency is merely a measure of physical fitness. The marathon runner only shows these signs after great exertion; the centenarian only avoids them by continual rest in bed. The broken-down heart presents both these signs all the time; it has no cardiac sufficiency at all.

Relative cardiac insufficiency arises when the circulation is unable to fulfil such demands as may reasonably be imposed upon it, having due regard to age, habit, and environment.

(*a*) *Age.*—The physical reserve diminishes as age advances. Football is a good game at 20, hard work at 30, and impossible at 40.

(*b*) *Habit.*—Dock labourers at 40 can endure physical exertion impossible to the cleric, barrister, and physician of the same age.

(*c*) *Environment.*—Vitiated atmosphere, adverse temperature, and unsuitable food all affect cardiac reserve. It is customary to refer such insufficiency to the heart.

The analogy of the circulation to the water-supply of a great city is always irresistible to me. We have heard much in the public press this year about London's water-supply, for it threatened to run short. Our water-supply, primarily derived from the rainfall, is collected into reservoirs and pumped through the supply pipes to each individual house, where it is used for cleansing in one way or another. Every house in London is supplied with water through a pipe. This provision does not necessarily keep the population any cleaner; they must themselves make use of the water in the proper way, exactly as the individual tissues must use their blood-supply in the proper way. When the rainfall fails the supply of water fails, and the best pump in the world cannot feed the pipes with water it has not got. Continuing the analogy, the output of the heart must be determined by its intake, a curtailment of which will cause the best heart in the world to fail. When the water pipes become old they suffer from two defects; (*a*) silting up, so that their bore is much reduced; and (*b*) a liability to burst, especially under stress. If the pump becomes defective and its valves leak, either the supply of water is curtailed or the pump must work harder and faster to maintain the supply. This simple analogy, therefore, offers four possibilities to explain an insufficiency of water-supply or blood-supply, the degree of deficiency being proportionate to the degree of the primary defect.

The Pump.

In considering the pump itself our analogy breaks down to some extent; it is obvious enough that if the pump be worn out and defective, or its valves become broken, damaged or actually destroyed, the pump cannot do its job and the water-supply fails. In this, of course, it exactly resembles the heart, but in the human body there is only one pump, which must do the work adequately for every demand made upon it. When an individual is lying in bed and asleep the demands upon his heart-pump are at a minimum, whereas when strenuous physical exertion is undertaken the demands upon the heart are enormously increased. The difference between the maximum and the minimum response can be regarded as the cardiac reserve. Relative cardiac insufficiency, therefore, is a diminution in cardiac reserve. This reserve power of the heart is best considered in terms of minute volume—i.e., the quantity of blood ejected by the heart per minute. This volume may be increased in two ways: (1) by increasing the frequency of the heart beat; and (2) by increasing the volume of blood thrown out per beat. The first of these is very easily observed; the second in man can only be arrived at indirectly.

Some estimate of the reserve capacity of the heart can be attained by observing in any individual the rise of pulse-rate which occurs in response to a standard exercise done at a standard speed. It is then found that the actual rise in frequency seems to be a measure of physical fitness. As a concrete example, a well-trained athlete will swing up and down touching the toes 20 times in 40 seconds, and show a pulse rise of 60 to 70 beats per minute, whereas an individual out of condition doing the same exercise in the same time will show a rise from 70 to 120 beats per minute. It is probable that the maximum frequency of the normal heart is 160 beats per minute, so that the reserve power remaining to the two individuals after the exercise is enormously different, and would become vastly more marked if the test exercise were more severe. Response to effort is, after all, the keynote of cardiac efficiency; in complete heart failure no effort is possible; the patient suffers a severe degree of distress even when kept completely at rest in bed and is unable to make even the slightest effort unassisted. His cardiac reserve is nil. At the other extreme the winner of a marathon race is endowed with a cardiac reserve beyond that of his fellows which reaches, of course, a very high order.

But the efficiency of the heart as a pump cannot be measured solely in terms of change of speed. There is another factor, the change in stroke-volume, and it is in this respect that the heart is so unlike the water-pump which formed our original simile. The volume of the blood ejected at each cardiac contracture can, and does, vary within wide limits.

Until a few years ago every text-book of physiology quoted Bowditch's law of the heart: that upon electrical stimulation the heart muscle responded either with the full force of which it was capable, or not at all—the "all or nothing" law. The brilliant researches of A. V. Hill have upset all our previous ideas of muscular contracture, and everyone now knows that the force of a muscular contraction is a function of its fibre length up to a critical destruction point. If we may apply that principle to the heart muscle, the force of its contracture will be determinated by the length of its muscle-fibres at the moment. Any lengthening of the cardiac muscle-fibre must, and will, result in an increase in the capacity of the chamber concerned, which will therefore hold more blood. It is important, of course, to bear in mind that muscle has no power of active relaxation and can exert no relaxation force, so that no question of suction in a muscular chamber can arise. There must, therefore, be some force to cause the actual increase of fibre length before this increased force is available. Muscle-fibre in relaxation will lengthen under a minimal force, but some distension force must bring this about.

Now general muscular exertion carries with it two factors: a demand for an increased blood-supply and a more rapid emptying of the veins, pressing the blood back towards the heart. Deepened respiration is another factor which is by no means insignificant. Immediately the return blood volume is increased, the amount taken into the heart in diastole is increased and in turn must and does increase the size of the muscular chamber, thereby increasing the length of each muscle-fibre and producing the one essential factor for an increased force of stroke and increased output volume. I believe that an appreciation of this automatic cycle is imperative for a due understanding of cardiac mechanics. The factor, then, in causing increased force of beat is the relative blood volume; in other words, the cardiac intake. Yet another factor is the force which a given mass of muscle can exert; this is very variable in different individuals and can be improved by training and use, and diminished by disuse and an unhealthy life.

Cardiac reserve, it now appears, may be expressed as the rise in force which accompanies a fixed degree of muscle lengthening, it being obvious that the heart muscle which gives maximum increase in force for minimal lengthening will always show the greatest reserve, other factors remaining equal. Variations in muscular capacity are apt to show themselves very clearly in the heart. The three outstanding processes affecting the efficiency of the cardiac muscle-fibre are: (1) Interference with the nutrition of the heart muscle—i.e., involvement of its blood-supply—i.e., disease of the coronary vessels. (2) Toxæmias: tobacco, possibly alcohol; influenza, and other toxic-infective diseases of which diphtheria is the outstanding example. (3) Inflammation of the heart muscle, as in the course of acute rheumatism, chorea, scarlet fever, and infective endocarditis.

There are two reasons why it is not easy to treat the after-effects of these damaging processes. In the first place, direct treatment to the heart muscle is not possible and any treatment must be indirect. Secondly, the heart is never given any rest: it cannot be put into one of those highly ingenious but far from ornamental glittering contrivances with which every orthopædic department in the country is littered. The inability to keep the heart at rest prolongs the toxic and inflammatory processes and renders recovery desperately slow. Treatment to help the recovery process and to improve the muscular tone must be a general graduated muscular exercise; walking is the easiest and most suitable, at least in the early stages, and is the method most usually adopted. The length of time required, not less than 12 months, is also a factor requiring much consideration and careful management. Once a heart muscle has been damaged by such toxic or infective processes its efficiency is materially reduced. In the terms of our definition: in order to produce extra force the degree of muscle-fibre lengthening becomes greater than normal; hence the fibres are liable to become unduly stretched in the heart's attempt to fulfil its obligations. This, in the old nomenclature, is cardiac dilatation. When to the process of muscle damage are added all the ill-effects of leaking, damaged, or destroyed valves, the nature of the total process becomes even more apparent and more fully appreciated.

---

* A paper read to the Incorporated Society of Massage and Medical Gymnastics.

The Defective Pipes.

A faulty pipe may burst, or may become so silted up as to pass only a much smaller volume of water than when it was new. The result of the burst pipe is familiar in that pathetic group of hemiplegics, whose pipes to the master tissue, the brain, have given way, causing widespread damage to the delicate nervous tissue and leaving the patient paretic alike in mind and body, but showing little or no direct effect upon the heart itself.

The silting-up process—arterio-sclerosis—reacts upon the heart in at least three different ways: (*a*) The arteries are reduced in calibre and elasticity, and the actual work done by the heart in forcing the blood through them is definitely increased—in other words, the cardiac muscle-fibres must lengthen to accomplish the task and the heart hypertrophies, or at least becomes longer. (*b*) The arteries deliver less blood to the tissue capillaries, less in fact than they actually need; the tissues in time cry out for more blood and set in motion that neurohormonic reflex which determines the blood-supply to each individual tissue according to its needs; this throws a further effort upon the heart. (*c*) If the coronary vessels, supplying the heart muscle, are themselves involved, the unfortunate cardiac musculature is starved of blood and its nutrition impaired at the same time as it is called upon to make an increased effort, so that further lengthening of fibre is necessary, greater force must be expended, cardiac reserve is encroached upon, and with such a vicious circle breakdown is not far distant.

When we approach the question of the proper use of the blood-supply by the tissues the issue becomes somewhat more complex. The water-supply of London will not keep the population any cleaner unless they wash themselves and their clothes both frequently and efficiently. The blood-supply to a tissue will not save it unless the tissue—to put it simply—can take up oxygen and *get rid of carbon dioxide.* Now damaged tissues are unable to discharge their function, and may thus have a far-reaching effect upon the whole body. As a concrete example, the kidney damaged by an attack of acute nephritis has a much reduced functional capacity. Although adequately supplied with blood, it fails to keep either itself or its body clean. The ultimate result is as disastrous to the body as to the city where members fail to make use of their water-supply.

Drought.

The water pumps of this great city cannot send out water which it has not got, and a drought inevitably embarrasses the water-supply of the whole area. The same is true of the heart. The force of the heart beat can only be increased by a lengthening of the muscle-fibre, and this lengthening must increase the size of the cardiac chamber and can never be an active muscular action. It then follows that no increase in the force of the cardiac cycle can possibly be produced without an increase in the volume intake of the heart. This can only occur under two conditions: (1) the return volume of blood must be increased; or (2) the filling-time of the heart—i.e., its diastole—must be prolonged. Now effort is always associated with a rise in cardiac speed, and the filling-time must, therefore, be shortened and the return volume of blood must be increased. Teaching about the circulation in the past has omitted the very essential factor of how this comes about, and yet it is really a simple mechanical problem.

Ventricular contraction drives the blood into the arteries, pressure being maintained in diastole by the elastic recoil of the larger vessels: thus the blood is forced through the capillaries and is collected up in the venules. Very little positive pressure is left in the vessels when the blood has travelled this far. Muscular contraction compresses the thin-walled veins of the limbs, and the valves with which they are furnished determine a movement of the venous blood towards the heart. In the legs this is accomplished against the force of gravity, so that it must be easier in the arms. In the head and neck gravity helps the return of blood towards the heart, but the abdomen, which contains a high percentage of the total blood volume, does not lie in between contracted muscles, even if its veins were furnished with valves, which they are not.

Once again I must refer to physiological principles, to what is known as reciprocal innervation. It is manifest that a forcible contraction of the flexor muscles of the arm or leg can only be effective when there is simultaneous relaxation of the extensor group, and these paired groups are said to be reciprocally innervated because when one group contracts the other automatically relaxes. The diaphragm plays a very large part in respiration; its descent would be difficult to accomplish were the abdominal muscles held firmly contracted. There is much evidence that a process of reciprocal innervation associates the diaphragm with the abdominal muscles. If this be true, then it follows that when on inspiration the diaphragm contracts, producing a negative pressure within the thorax, at the same time the intra-abdominal pressure is raised to some degree by its descent. Meanwhile the abdominal muscles relax to some extent, so that the great abdominal veins are slightly compressed on the abdominal side while the intrathoracic pressure falls, and blood passes into the thorax. With quiet expiration elastic recoil is usually considered to be sufficient to account for the process, but immediately expiration is at all forced the abdominal muscles come into play and raise the abdominal pressure, thus forcing the diaphragm up into the thorax. Here, then, we have a very definite mechanism tending to return blood to the heart—in other words, to supply blood direct to those venous cisterns, the great veins, which deliver blood direct to the auricles for supply to the ventricles. The act of respiration is a very definite force which during inspiration draws blood into the thorax by negative pressure and during expiration raises the intra-abdominal pressure to the same end, but to a lesser degree.

It is common knowledge that muscular exertion deepens respiration, and that expiration becomes active rather than a mere passive recoil. Here we have again one of those nicely balanced mechanical arrangements with which natural phenomena in the body are so commonly equipped. Effort demands increased blood-supply; muscular contraction speeds up the blood return through the veins; respiration is deepened, increasing the thoracic suction power and raising the intra-abdominal pressure, thus driving the blood from the great abdominal veins into the thorax; the return flow of blood to the venous cisterns formed by the venæ cavæ fills them with blood; more blood passes into the auricle and is sent into the ventricle, thus causing an increased stretching of the ventricular wall, a lengthening of its muscle-fibres, and an increased power of stroke. In this way the output of the heart is increased both in speed and volume, and the tissues are served.

The venous cistern consists of all the great veins—cavæ, innominates, hepatic, and iliac—and is closed by six valves in pairs at the femorals, subclavians, and jugulars. In the lower animals there is a venous sinus, shut off from the auricles by valves, and it is highly significant that as we pass up the animal scale the disappearance of the sino-auricular valves coincides with the development of a diaphragm. There is therefore phylogenetic support for our belief that the return flow of blood to the heart's reservoir is a function of the diaphragm. The size of this reservoir is very great, and its capacity is estimated in man as 1400 c.cm. It can therefore be called upon to give an immediate response when effort is demanded of the heart.

This is not the only force attracting blood to the heart and acting to fill the heart chambers. The pericardium is a strong fibrous bag, and negative intrathoracic pressure can be shown to affect the pericardium and so cause aspiration of blood into the auricle. It probably does not act upon the *ventricle,* the walls of which are too thick and powerful. Further, each time the ventricle contracts and empties itself it must of necessity cause a negative pressure inside the pericardial sac, a pressure determined by its volume output; this ventricular emptying at each systole will automatically tend to fill the auricles, since they are thin-walled, are in diastole, and are enclosed within the fibrous pericardium. These, however, are small forces and are not of such great value in moving large volumes of blood. They probably only act upon the blood quantum in immediate juxtaposition to the auricles.

Cardiac Reserve under Conditions of Valvular Defects.

When the aortic valve becomes incompetent the ventricle contracts and drives a certain amount of blood into the aorta. During diastole a certain proportion of this blood escapes back into the ventricle, which also receives its usual change of blood from the auricles. Thus more blood is pressed into the ventricular cavity, which in turn expands; the muscle-fibres are duly lengthened and an increased stroke-output results. In this way the regurgitant quantity of blood is compensated for, but the heart is working with a longer muscle-fibre; hence when call comes for increased rather than merely descriptive names, for by doing so one is apt, as it were, to embalm a fallacious theory and give it an appearance of life most misleading to the inexpert and the unwary. The term concussion perpetuates the view that the familiar instantaneous traumatic paralysis that goes by that name is due to the brain having been shaken about inside the skull and having sustained some mysterious though happily transient detriment thereby. Judging by the evidence now available and with the proper reservation as to the provisional nature of all scientific statements, it may be asserted categorically that the doctrine conveyed by the word concussion is not correct, and that the state in question is due to the momentary and general anæmia of the brain that accompanies a general distortion of the skull.

THE MIDDLE PERIOD: COMPRESSION OF THE BRAIN.

The next phase in the evolution of the surgery of head injuries brought to its problems the help of the experimental physiologist and was to transform the subject from a largely empirical art into something approaching an applied science. In the latter part of the last century was begun by experimental methods the attack upon the fundamental problems of intracranial physiology with which we associate such names as those of Horsley, of Leonard Hill, of Kocher, and of Cushing. Such work gave us the essential facts about the peculiarities of the cerebral circulation and especially the importance of the venous side, it showed that circulatory disturbance is the chief mechanism by which cerebral symptoms are produced, and it taught us what symptoms are produced and how they are produced by a progressive lesion compressing the brain. All these are fundamental principles and of the most direct practical importance, and yet it must be admitted that they did not result in as much progress on the clinical side as they seemed to promise, or in the general elucidation and simplification of the subject for the student that they really rendered possible.

The comparative failure in the fertilising power of the new knowledge was perhaps in part due to two causes. In the first place the exposition of the new doctrines was apt to seem to the clinician abstruse and remote from practical reality—a difficulty that will be understood by those who have read Kocher's classical monograph. And in the second the subject was so much dominated by the theory of the localised compressing lesion that the student was apt to get the impression that the localised hæmorrhage that lends itself to successful operative treatment was the usual form of head injury with which he would be called upon to deal. Such cases of local hæmorrhage without other serious injury do, of course, occur, and thanks to the experimental school our understanding of them is very full and we can usually recognise and deal with them with brilliant results. But they are rare and form but a very very small proportion of the cases of head injury we meet with in practice.

We see, then, that the surgery of head injuries has inherited from what we have called its middle period, in addition to an invaluable treasure of the principles of cerebral physiology and pathology, a fallacious clinical impression that head injuries are largely a matter for urgent operations which can and should be undertaken in a considerable proportion of cases with reasonable expectations of success. It is the melancholy duty of anyone making a reasoned survey of the subject to discourage this still widely prevalent view.

THE MODERN PERIOD: CONTUSION OF THE BRAIN.

In order to give perspective to this very much condensed survey some notice of the more characteristic features of a present-day view of the subject is necessary. In the interests of simplification this purpose may perhaps be effected by commenting briefly on some three themes each of which may fairly be regarded as typical of the modern surgery of head injuries. These three themes are (1) the simplification of the theory of the subject and its closer relation to clinical actualities; (2) the recognition that the typical cerebral lesion of a head injury is in the nature of a contusion, local or widespread, superficial or substantial or both; (3) the emergence into clinical recognition of the minor and the unresolved contusion as definite entities capable of exact diagnosis and treatment.

The Simplification of Theory.

Expositions of theory that have come down to us from the experimental school contain undoubtedly the principles that are necessary to a practical grasp of traumatic cerebral lesions. Yet there can be few of us but must have been aware, after reading these acknowledged classics, of an uneasy sense that the confused and multitudinous events of our clinical experience have still refused to take on order and significance. Or again, how often have we not felt by the bedside the difficulty of reconciling the supposed precepts of our masters with the versatility of nature in producing symptoms that had no right to be there or in withholding symptoms that we had every claim to expect.

Some of these troubles were doubtless due to the mechanisms of cerebral lesions having been regarded too much as in a province apart and completely sui generis. It is true that the functional relations of the brain and skull are, strictly speaking, unique in the body. Looked at more broadly, however, the two make together merely an extreme case of the encapsuled organ. Viewed as an organ with a capsule completely rigid (to physiological forces of course) the brain is no longer the seat of circulatory mysteries of which the very exposition must be obscure. In an encapsuled organ of the ordinary type such as the kidney the continuous flow of blood is kept up by the capsule being extensible and elastic and permitting an expansion of the whole organ at each arterial pulsation. The rigidity of the skull makes some other mechanism necessary there; this is provided by the presence of a considerable low tension region between brain and skull (broadly speaking the subarachnoid space and the venous channels) which permits the brain to expand with each arterial pulse. This low tension space is just adequate to allow the full normal pulsations of the brain; the tension within it is that of the venous pressure which it constantly follows. Crude as this exposition has been designedly made it gives us an easy explanation of two outstanding anomalies—the normal presence of arterial pulsation in the intracranial veins and the singular extent to which the adequacy of the cerebral circulation is at the mercy of its venous side. It is this sensitiveness to any interference with the venous return which makes a mere bruise of the brain a serious lesion both because of its power of causing symptoms and because of its extreme slowness in resolution. A more striking and less familiar way of stating the same physiological facts is to say that the brain is the only organ in the body which, after injury, must return to exactly its normal size before it can function normally.

While the rigidity of the cerebral capsule is truly unique there is one interesting case of an organ—the testis—which shows a distant approximation to it. Here we find two of the characteristics otherwise limited to the brain—the risk of extreme disorganisation in sequence to a simple bruise and the liability to hernia formation when the organ is swollen and the capsule perforated.

Contusion the Typical Traumatic Lesion of the Brain.

In giving to each of the periods I have called attention to a somewhat arbitrary title, I have added as a sub-title the lesion with which in each particular phase observers have been especially concerned. Present-day views of head injuries leave no doubt that in dealing with them contusion of the brain should occupy this position.

The importance of distortion of the skull in the causation of brain injury has made it clear that in addition to the long recognised direct and polar (or contrecoup) bruising to which the brain is liable under violence, the whole organ is subject to stresses and deformations which must expose its whole surface and substance to damage. After any injury at all severe it is probable that widespread bruising is always present. Such bruising, though not in itself a seriously destructive lesion, gains very rapidly in the gravity of its effects according to the extent to which the parts of the brain in the posterior fossa of the skull are involved. It is contusion here which is perhaps the most common cause of death and the most common cause of ultimate failure in apparently successful operations for hæmorrhage. In every case of severe injury all the clinical manifestations are, as it were, sketched on a background of contusion phenomena of all grades of definition. While contusion is so largely responsible for the gravity of head injuries, it has in comparison with gross hæmorrhage one very favourable character. This is that it can in its very nature scarcely give rise to pressures beyond the order of the venous pressure. It cannot, therefore, produce gross capillary anæmia and the accompanying paralytic states.

Thus contusion rarely calls for urgent operations, and in so far as it is amenable to treatment at all can and should always, at any rate in the early phases, be dealt with by milder measures. The range of severity of symptoms to which contusion can give rise is very wide, and we have now at our command a wide range of remedies none of which we can afford to ignore. Familiar as these now are the list of them cannot be too often repeated, and I give it with the remedies arranged roughly in the order of increasing severity of symptoms to which they are applicable—*rest; posture; hypertonic derivation—(oral, rectal, or intravenous); lumbar puncture; decompressive operation.* None of these measures can we afford to neglect, and each single one of them is at times capable of giving brilliant results.

The Clinical Recognition of Unresolved Contusion.

During the late war there developed a strong and healthy tendency to the general recognition of the fact that many conditions to which a vague organic pathology had long been assigned were actually true psychoneuroses. It is interesting to note that during the same period in the surgery of head injuries a process in exactly the opposite direction was taking place. A large group of clinical phenomena that had previously been assigned to the uninviting chaos of "traumatic neurasthenia" was found to be due to definite organic brain injury in the nature of minor and unresolved contusions of the brain substance.

Not less interesting from the point of view of the theory of knowledge was the fact that as soon as the true pathology of these states was known, their symptoms, which had been regarded as essentially elusive and indefinite, were found to be well defined, capable of exact description, and forming a characteristic clinical picture; here I need remind you only of its three characteristic elements—headache, giddiness, and minor mental changes. It is a common, indeed a very common, result of head injury of any grade of severity. Its development can often be prevented or greatly modified by precautionary treatment, and in its developed state in typical cases diagnosis is exact and treatment efficacious. The unresolved contusion shows itself as an indefinitely persisting but variable elevation of the intracranial pressure. As such its symptoms have that close dependence upon the state of the venous pressure that the studies of the experimental school had proved must be present in such circumstances. The elucidation of this troublesome clinical problem is thus perhaps the latest gift we owe to the distinguished band of experimental investigators whose work through so many years continues to fertilise this difficult and stubborn field. The surgery of head injuries can never be easy or popular, but in its foundation of scientific theory it has a treasure which may well be the envy of every other branch of our art.

LACTIC ACID AND CARCINOMA OF THE STOMACH.

BY E. C. DODDS, M.V.O., M.D., PH.D. LOND.,
COURTAULD PROFESSOR OF BIOCHEMISTRY IN THE UNIVERSITY OF LONDON; CHEMICAL PATHOLOGIST TO THE MIDDLESEX HOSPITAL;

AND

J. D. ROBERTSON, M.B. ST. AND., D.P.H.,
ASSISTANT CHEMICAL PATHOLOGIST TO THE MIDDLESEX HOSPITAL.

(From the Courtauld Institute of Biochemistry.)

IT has been usual to be influenced towards a diagnosis of carcinoma of the stomach by three findings in the gastric contents—namely, achlorhydria, foulness with the presence of blood, and the presence of lactic acid. In this paper we do not propose to enter into an historical review, but merely to recount the results of gastric analyses in both malignant and non-malignant cases with special reference to the presence of lactic acid. In a previous publication[1] we have shown that the qualitative tests for lactic acid are unreliable. The problem was attacked from a quantitative point of view, and a method for the detection of lactic acid and its estimation in small quantities was described. We were able to show that 40 per cent. of the resting juices of a series of non-malignant cases contained lactic acid, while the later specimens of the fractional test-meals of the same series showed 36 per cent. to contain this substance. All the cases of carcinoma of the stomach investigated in this series were found to contain lactic acid. These findings threw considerable doubt on the theory that lactic acid is produced specifically through the presence of the carcinoma in the stomach. In one case only was it found possible to isolate the actual lactic acid present as a zinc salt, and the chemical examination of this proved it to be of the inactive variety. This pointed very strongly to a fermentative origin of the lactic acid, and argued equally strongly against its being produced by the metabolism of the cells of either the gastric mucosa or the carcinoma; for, if this were so, we should expect to find lævorotatory acid—namely, sarcolactic acid. It was pointed out that this was an isolated observation, and that work was in progress on other cases of carcinoma in order to verify this fact.

The objects of the present communication are as follows: (*a*) to determine the type of lactic acid produced in a series of cases of carcinoma, and thereby to trace its origin; and (*b*) to confirm or refute the statement that lactic acid can be produced very rapidly in the stomach. This is important because rapid production would appear to argue against its origin by fermentation.

Method.

All the patients were examined by the fractional method of gastric analysis. Two charcoal biscuits were given at 10 P.M. on the night before examination. After withdrawal of the resting juice, the stomach was washed out by the injection of water down the tube, followed by aspiration. Lactic acid was estimated by the method already described,[1] and the zinc salt was isolated according to the technique of Warburg.[2] The zinc salt was examined for its rotatory power, its water of crystallisation, and its ash content (ZnO).

Results.

(*a*) *Type of Lactic Acid.*—The patients investigated were seven in number, and included five cases of proven carcinoma of the stomach and two cases in which this condition was definitely excluded. The results are given in Table I., where it will be found that the lactic acid in every case was of the inactive variety, which points very strongly to a fermentative origin.

Lævo Zn. lactate.	$\left[\alpha\right]^{20}_{D} -6{\cdot}8$	12·9	33·4
Dl. Zn. lactate.	0	18·2	33·4

(*b*) *Obstruction and Lactic Acid.*—Table II. summarises 12 cases of gastric carcinoma, showing the lactic acid in the resting juice. All cases had achlorhydria. It also states whether the patient had obstruction or not, the diagnosis of obstruction being based on either the radiological findings or the fractional test-meal. It will be seen that the cases with obstruction had a very much greater quantity of lactic acid than those without. Where, however, there was no stenosis, the amount of lactic acid was often less than that found in some of the non-malignant cases reported in this and in our previous paper. It is felt that this is still further evidence in favour of the fermentative theory for the origin of lactic acid.

Rapidity of Production of Lactic Acid.

The foregoing results seem to establish almost beyond doubt that lactic acid in the stomach is produced by fermentation. Only one argument against that theory remains to be overcome—namely, the statement of certain workers that lactic acid may be produced very rapidly in the stomach. It is declared by some that if the stomach of a patient with carcinoma is washed out, lactic acid will appear in appreciable quantities within half an hour of administering the test-meal. If this were true, it would throw a good deal of doubt on the fermentative theory; and it will be seen that our earlier cases appear to support the statement. Thus in the cases illustrated in Figs. 2, 3, and 4 appreciable quantities of lactic acid are produced towards the end of the test-meal, despite the fact that the stomach was washed out with water immediately after collecting the resting juice. It will be noticed, however, that the much-referred-to "disparity" of the later specimens is nothing like so marked as in cases published by other workers. We believe this is due to careful washing of the stomach, and we formed the idea that the greater the care taken in washing out the stomach, the less would be the disparity in the later specimens. A careful inspection of the stomach removed from one of our patients in the post-mortem room indicated the extreme difficulty of washing out such a stomach by the ordinary method. It contained a large growth which formed recesses and pockets which would be inaccessible to the ordinary washing out process. It was easy to see that during the later stages of the meal these pockets and recesses would discharge their contents into the main pouch of the stomach, with the result that lactic acid would appear with considerable rapidity, and thus lend support to the argument that it was secreted.

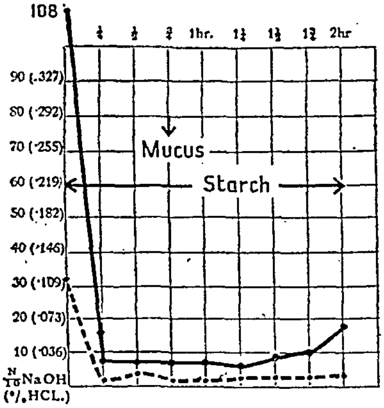
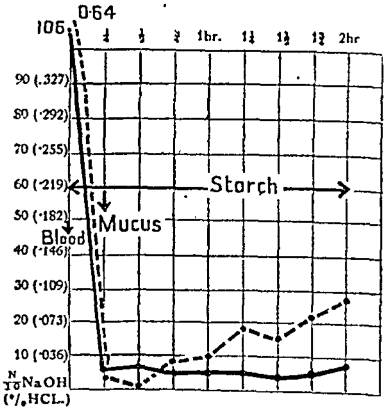
* L.A. = Estimation of lactic acid in resting juice after 12 hours fast in g. /100 c.cm.

FIG. 1.



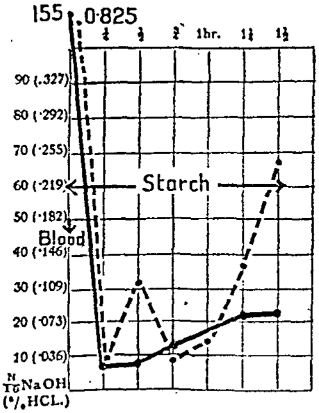
CASE 1.—Carcinoma ventriculi. Resting juice: volume 370 c.cm., odour foul, charcoal present, blood present. Residue: 370 c.cm. at end of two hours.
N.B.—In this and subsequent figures the continuous lines represent total acidity, whilst the dotted lines (figures in decimals) represent lactic acid.

FIG. 2.



CASE 2.—Carcinoma ventriculi. Resting juice: volume 650 c.cm., odour butyric, charcoal present, blood present. Residue: 250 c.cm. at end of two hours.

FIG. 3.



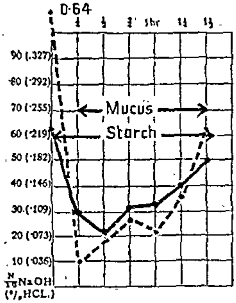
CASE 3.—Carcinoma ventriculi. Resting juice: volume 650 c.cm., odour foul, charcoal present, blood present.

It was decided to investigate the next patient by a special method with a view to washing the stomach as clean as possible. By the ordinary technique of injecting water down a tube and aspirating it, it was found impossible to reach a point at which the washings were absolutely free from starch and lactic acid, therefore it was obvious that this method had to be improved. A series of experiments showed that very efficient washing could be obtained by getting the patient to swallow two tubes, down one of which an assistant injected warm water, whilst the operator aspirated continuously at the other tube. By repeatedly altering the position of the tubes—by pulling them up and asking the patient to swallow them again—it was found possible to wash out the stomach very thoroughly indeed, and after continuing this vigorous treatment for 1–2 hours, and using from 6–7 litres of water, it was found that the washings were absolutely clear and gave no reaction for starch or lactic acid. This method was applied in the case illustrated in Fig. 1, and the chart shows that the resting juice contained a very large quantity of lactic acid with a very high total acidity. After collection of the resting juice the stomach was washed out by the technique described, and it will be seen that the later specimens of the fractional test-meal contained very little lactic acid. This disproves the statement that this substance is produced very rapidly, even after washing out the stomach. It remains, however, to corroborate that the high concentration of lactic acid in the resting juice is due to fermentation and is not produced through secretion. This problem was attacked by taking the same patient and washing her stomach out very carefully by the two-tube method at 7 o'clock one evening. This was done until the washings were absolutely clean as described. At nine o'clock the next morning a tube was passed and the resting juice was collected. The analysis of this specimen was as follows :—

Volume ..	70 c.cm.	Bile	Positive
Odour ..	Normal	Free HCl ..	Absent
Blood ..	Positive	Total acidity	6·5 c.cm. N/10*
Mucus ..	,,	Lactic acid ..	0·006 g.*

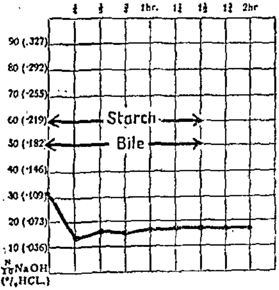
*per cent.

FIG. 4.



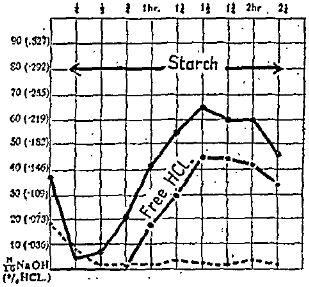
CASE 4.—Carcinoma ventriculi. Resting juice: volume 650 c.cm., odour foul, charcoal present, blood present.

FIG. 5.



CASE 5.—Chronic appendicitis (laparotomy). No lesion of stomach. Resting juice: volume 74 c.cm., odour foul, charcoal present, blood absent, bile present. Residue: 220 c.cm. Resting juice and stomach washings: Lactic acid estimated at 0·076 g. per 100 c.cm., 140 c.cm. gave 0·11 g. zinc lactate. Water of crystallisation, 18·1 per cent.; ZnO, 33·7 per cent.

FIG. 6.



CASE 6.—Migraine (stomach normal on repeated radiography). Resting juice: volume 200 c.cm., odour normal, charcoal absent, blood absent, mucus present.

It will be seen that it is in every way unlike the resting juices of the cases of carcinoma of the stomach, for the volume is relatively small, there is no foulness, and although free hydrochloric acid is absent, the total acidity is only 6·5 c.cm. N/10 per cent., as against 108 c.cm. N/10 per cent. on the previous occasion, whilst the quantity of lactic acid is extremely small. We were able to confirm this observation in Case 7. His stomach was washed out by the same technique at 7 o'clock one evening, and the resting juice was collected at 9 o'clock the following morning. The following is the result of the analysis:—

Volume ..	20 c.cm.	Free HCl ..	Absent
Odour ..	Normal	Total acidity	7 c.cm. N/10*
Blood ..	Positive	Lactic acid ..	0·008 g.*
Mucus ..	,,		

*Per cent.

It is felt that these observations completely prove the claim that lactic acid in the stomach is produced by fermentation and not by secretion. It is, therefore, justifiable to consider the rapid appearance of lactic acid after washing out the stomach to be solely due to inefficient washing, with the result that lactic acid, &c., enters the main stomach from the various crevices and pouches formed around the growth.

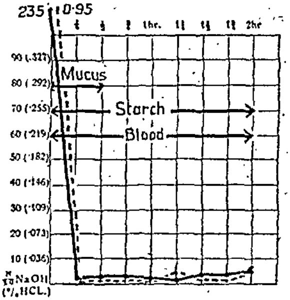
Summary and Conclusions.

1. Examination of a further series of cases has confirmed the opinion set forth in a previous communication, that lactic acid is found in non-malignant diseases of the stomach as well as in carcinoma.

2. The lactic acid in seven cases has been isolated in the form of a zinc salt, and by chemical analysis has been found to be of the inactive variety. This applies to non-malignant as well as malignant cases, and supports the fermentative theory for its origin.

3. The only remaining difficulty in the way of the fermentative theory is the claim by many workers that lactic acid is secreted very rapidly even after washing out the stomach. Evidence is brought forward that it is very difficult to wash out the stomach of a patient with carcinoma properly, owing to the number of crevices and pockets around the growth. If, however, the technique described in the paper with two tubes be employed, it will be found that the amount of lactic acid in the latter specimens of the test-meal is negligible, and the total acidity is very low. These observations would indicate that the lactic acid is not secreted rapidly, but appears in the test-meal in appreciable quantities only if the washing has been insufficient and stagnant contents enter the main lumen from the various recesses and pockets around the growth.

FIG. 7.



CASE 7.—Carcinoma ventriculi. Resting juice: volume 760 c.cm., odour foul, charcoal present, blood present, mucus present. Residue: 240 c.cm. at end of two hours.

4. If the stomach of a patient with carcinoma be washed out (by the technique described) on the night before the test-meal, it is found that the resting juice collected 12 hours later contains practically no lactic acid. This is evidence that neither the stomach mucosa nor the growth are capable of producing lactic acid by themselves even in 12 hours. It is interesting to note that there is no evidence of foulness in the resting juice of patients so treated.

5. If the lactic acid content of the resting juice be contrasted with the clinical and radiological evidence for obstruction, it is found that the lactic acid content is very much greater in cases with obstruction than in cases without.

6. It is felt that these observations prove that the lactic acid is produced through a fermentative action combined with pyloric obstruction, and is, therefore, of little or no diagnostic value for carcinoma of the stomach. In support of this it is found that the lactic acid content in cases of carcinoma with no obstruction is often less than that found in non-malignant diseases.

It is a pleasure to acknowledge the kindness of Dr. G. E. Beaumont and Dr. T. Izod Bennett, who gave us permission to investigate their patients. We have to thank Mr. E. J. Gallimore for assistance in the analysis of specimens, and in preparation and examination of the zinc salt. We also wish to express our gratitude to the Halley-Stewart Trust Fund, which provided the apparatus, and a considerable amount of the assistance, for this investigation.

THE HUMAN MACHINE.

ITS EFFICIENCY AND LIMITATIONS.*

By ADOLPHE ABRAHAMS, O.B.E., M.D. CAMB.,
PHYSICIAN TO OUT-PATIENTS, WESTMINSTER HOSPITAL;
PHYSICIAN TO THE HAMPSTEAD GENERAL HOSPITAL.

I AM interested in myself, my machine, because it is mine. Moreover, as a medical man I am occupied in assisting to maintain the efficiency of machines; to ascertain causes of a breakdown; to recommend such repairs as I think likely to restore efficiency completely or to the best of the potentialities of the material. In some respects the doctor is the mechanic at a garage, but with this difference, of course. The mechanic being a workman can repair machines made by workmen like himself; only Nature can repair the Nature-made machine.

A Comparison with the Internal Combustion Engine.

I propose to attempt some comparison of the human machine with the internal combustion engine, but with the full realisation that the analysis must not be pressed very far. As soon as one reaches purely vital phenomena comparisons must break down; and in the case of the human being, additional complexity is introduced by the highly organised nervous system with its necessary frailties, its likes and dislikes, its whims and fancies, its hopes and fears. Nevertheless, I think this attempt should deserve your sympathy partly because we are not in serious philosophic contemplation this evening, and partly because I regard it of value for people occasionally to consider their bodies from a mechanical aspect.

To this extent, at any rate, analogy holds good. Inefficiency in the motor-car is often the result of faulty construction; inefficiency in the human machine may similarly be fundamental. In both human and mechanical machinery a construction originally satisfactory may be damaged, more or less irreparably, by neglect or misuse. And, finally, both are under the influence of environment: variable road surfaces in the case of the motor-car; a multitude of conditions in the case of the human machine.

That these strictly analogous circumstances are not generally realised is the everyday experience of the doctor compelled to encounter many unreasonable complaints and expectations.

Recently a physicist has taken it upon himself to reproach the medical profession because of its inability to prevent heart disease or provide better aids to defective eyesight than spectacles or more efficient attempts to cure deafness. This physicist is an expert motorist, and he ought, therefore, to appreciate the difficulties of those who minister to human machinery, since he is confronted with similar propositions in his own sphere. What would he think of a complaint that an engine put together out of originally defective material which had undergone a severe injury to its lubricating apparatus and the design of which was more appropriate to a commercial than a racing chassis, was incapable of climbing a test hill on top gear, or of running for 200 miles at 40 miles an hour without an involuntary stop? Or of a request to perform some sort of operation upon a tyre which had been in continuous use for 15,000 miles over rough surfaces, and restore it to the condition in which it left the works?

To compare vital issues with non-living material is to some minds repugnant in any circumstances. To others the comparison is only too welcome. There is one type of mind which thinks statistically and believes that the wonders of the human machine can be best conveyed by some such statements as that the blood-vessels of the lung if stretched out in a line would extend half-way to the moon; or that the red corpuscles if laid out flat would form a carpet so many inches wide and so many miles long, a form of measurement which to me personally has no significance whatever. There is another type of statistics, a sort of contemptuous materialism, in which the components of the human body are estimated in the following homely fashion. An average man's body weighing 10 stone is composed of enough water to fill a 10-gallon barrel, enough fat for seven bars of soap, carbon enough for 9000 lead pencils, and phosphorus enough to make 2200 match-heads; magnesium enough for one dose of salts, iron enough to make one medium-sized nail, lime enough to whitewash a chicken-coop, and sulphur enough to rid one dog of fleas. The whole at post-bellum prices could be purchased for five shillings. And the same statistician might have completed his summary by pointing out that it was much the same whether the body in question was that of a village idiot or of an Einstein.

Human and Animal Achievement.

Fortunately for one who would be horrified at the idea of attempting to consider the almost unlimited capabilities of the human machine on the intellectual side, this aspect of the matter is unnecessary in the present consideration. But it is easier and not without interest to enumerate some of man's achievements on the physical side in which connexion he may logically be regarded as a machine. Now admittedly things of flesh and blood cannot compete with non-living machinery; man, too, comes off badly in comparison with many of the lower animals. The development of the large brain together with the assumption of the erect attitude put man at many mechanical disadvantages. The wonder is that in the circumstances his achievements are so noteworthy. Man, in his choice for comparisons, pays deference to the lower animals, not merely on the physical but on the mental, and even the moral, platform—indication of his protean qualities. And it must be claimed for him that, whereas his specialised functions have in some respects been severely detrimental to his physical possibilities, man is still capable of some remarkable performances. One remembers that, although the cheetah is credited with a speed of 60 miles per hour, a velocity equalled by the greyhound, and that a horse has achieved approximately 40 miles per hour, few animals can beat a crack sprinter at his fastest—travelling 11·42 yards per second—23·3 miles per hour.

---

* An address delivered to the Guild of Public Pharmacists on Jan. 22nd, 1930.

At longer distances, man's capability becomes even more conspicuous. He has run 112 yards short of 12 miles in the hour; 100 miles in less than 14½ hours, and in a "go-as-you-please" six days' contest has covered 624 miles, a feat which no horse could achieve. One has also to record the remarkable record of 3422 miles in 573 hours during the race across America in 1928. It is difficult to obtain reliable statistics of jumping capacities of animals not specially trained, but 8 ft. 2 in. appears to be a horse's record high jump, so that man's 6 ft. 8¼ in. is highly commendable. The horse's long jumps recorded are often apocryphal, but man we know for certain has cleared 26 ft.

Feats of endurance of the human machine are a striking tribute to the quality of the material and the adequacy of the lubricating system. It has been recorded that the piano has been played continuously for 120 hours, and one hardly knows whether this is a more remarkable achievement than swinging Indian clubs for the same length of time. The human machine, unsuited as it is for an amphibian existence, has swum for over 27 hours during a successful Channel swim. And whilst a record for staying under water for no less than six and a half minutes has been doubtfully claimed, there can be no question that four and a half minutes has frequently been achieved.

All sorts of tests of endurance may be and have been devised in a fantastic search after records. In this connexion one may mention the records of fasting men, whether as a music hall event or as a protest against political or legal coercion. But it is profitless to speculate upon the extent to which a machine, whether human or otherwise, may deliberately be abused and injured.

Sex Differences.

One must at this stage be prepared to say a few words upon the differences between man and woman as a machine, a subject of immense complexity on the psychological side and therefore temptingly appropriate in its reduction to something approaching fundamentals when anatomy and physiology are considered. It is perhaps unfortunate that in this respect conclusions must inevitably be based upon inadequate evidence. Protagonists of violent exercise for women are over-ready to compare the capabilities of the best woman with the average man, very much to the latter's disadvantage. We cannot compare the average man with the average woman, because the average woman does not supply material for this physical consideration, but we can utilise for the present argument the best achievements of each.

A record-breaking young woman has, during the course of a 100 yards race, attained a maximum velocity of 19·4 miles per hour (man's highest speed 23·3 miles per hour). Incidentally, it is interesting to reflect that sex does not appear to affect the physical capabilities of quadrupeds for the speed of the female equals that of the male. Woman's record high jump is 5 ft. 3 in.; her best long jump is 18 ft. 8 in.—i.e., considerably inferior to man's best, but far above man's average. Feats of endurance for women are deprecated, somewhat illogically for there is no reason to suppose that woman is less adapted than man in this respect. On the contrary, she appears to be capable of enduring moderate physical hardship of long duration better than man. The exploits of women as channel swimmers have only to be recalled in this connexion; women mountain climbers have almost equalled men in their accomplishments, and I believe that a female Arctic expedition would be eminently successful. Young women's cross country clubs are now commonplace, though long distance running is, on the whole, discouraged. One girl has been credited with the ability to run over the Marathon course of 26¼ miles in 3 hrs. 40 mins. 50 secs., a feat which I am disposed to doubt, though I do not doubt the possibility.

The Fuel.

In comparing the human machine with an internal combustion engine, and seeking analogies for the various parts, one's progress is at first smooth for one's similes are logical. The motor-car utilises the vapour of petrol as a source of energy. Petrol is selected because it is a readily oxidisable fuel, and regarded as a foodstuff is, so to speak, predigested. The motorist knows that there are grades of spirit, some promising (often with truth) to yield more power than others. The fuel of the human machine, from whatever source derived, is ultimately an easily oxidisable substance, glycogen; and whereas the petrol engine has no palate and establishes as a primary demand only that its fuel shall be clean and free from sediment, the human machine is more discriminating; and even if the ultimate source of energy be the same, the materials from which it is derived may and must vary considerably. It is not always realised that different human machines require different varieties of fuel. For strict comparison with the petrol engine we should visualise man as an ideal machine only when he becomes an ethereal mortal living on nectar, when his alimentary canal would be reduced to the condition of the feed-pipe of the motor-car. It is easy to supply reasons why this conception of man will never be realised. The whole food question must be bluntly dismissed in a thesis dealing solely with human machinery. For, reduced to fundamentals, the food supplied as fuel to the human machine is that stored up in the petrol tank, having been elaborated from the variable raw materials presented to it for digestion. This specialised part of the machinery has, in a way, nothing to do with its ultimate efficiency. The essential is the preparation of the fuel and the raw material from which it is prepared varies with the individual. From this we understand the fallacy of dogmatism—one individual will utilise as an optimum, raw material which would be inadequate, and even harmful, to another. Men capable of achieving first-class athletic results upon what may charitably be called freak diets, are too prone to suppose that their experience is not merely individual. And so adaptable are the human laboratories that the diet question is really insignificant so long as ordinary sensible regulations based upon the past experiences of many generations are followed.

Even at the present day a battle is perpetually being waged on the question of the best diet for physical exertion, and many old traditional ideas become translated into the terminology of vitamins and other modern discoveries. If there is one generalisation which may be permitted it is to allow the appetite and tastes of the individual to follow their natural inclination, and to deprecate Procrustean measures of any kind whatever.

Its Utilisation.

And now in our consideration of the fuel problem in our comparison of man and motor we encounter an essential difference in the method of utilisation.

In the motor-car, petrol is fed from the tank to the carburetter, where it is prepared (by admixture with air) for oxidation, and then passes to the cylinders. This suggests the passage of food to the stomach where it is prepared for assimilation and passed to the active tissues. But whereas in a petrol engine oxidation precedes work, in a muscle work precedes oxidation. The muscle may be regarded as a storage battery working on energy previously stored. Contraction breaks down sugar into lactic acid, which, by subsequent oxidation, becomes carbon dioxide and reconverted sugar and glycogen. And whereas in violent exercise a certain amount of lactic acid remains in the muscles to be oxidised at rest, the provision of an adequate supply of circulating blood with oxygen is indispensable through the arteries (the inlet valves) into the muscles (the cylinders), and out by the veins (the outlet or exhaust). Just as the bore and stroke of the cylinder determine to a great extent the power of the car, so the efficiency of the muscles makes the human machine a good or a bad athlete. But with living tissue there is quality as well as quantity. The muscles of a naturally gifted highly trained athlete possess special qualities—for example, better contractility and the capacity to tolerate lactic acid, qualities which are not easily described in terms of mere machinery.

For oxidation ignition must occur. In the human machine the magneto is the brain which, notwithstanding its complexity of working in relation to the whole mechanism, may for simplicity be regarded here as purely a means of ignition. From it impulses pass down the nerves (copper wires) to the terminations in the muscles (sparking plugs). The man who can run or row or perform any well-coördinated act is the man-machine with a perfectly timed magneto. And whilst such timing is to a large extent his natural heritage, training for athletics is an education of the brain to send out the proper impulses.

The blood (in addition to its other qualities) is the lubricating oil, and the heart is the pump. The radiator is obvious; the whole of the body is the human radiator exposed as it is to surrounding media, and keeping the engine cool by evaporation from the surface. With excessive heat production the radiator boils—that is to say, the human machine perspires.

The transmission, gears, and wheels are comprised in the tendons, joints, and bones. Legs are a sorry substitute for wheels in some respects, but they are admirably adapted for the large variety of purposes they are called upon to fill. Broadly speaking, the human machine has a fixed gear, one depending upon the relative proportions of the parts of the lower limb, and particularly on that of the heel to the front pillar of the foot. If we could alter the length of the heel at will we should possess a variable gear. We find that in the sprinter the front pillar is relatively long, so that the leverage gives great power to the calf. In the long distance runner the relatively long heel gives less leverage but a better sustained effort—a short stride with proportionately little exertion.

Admittedly all these analogies are very elementary; scope for amusement, perhaps, rather than instruction. Any attempt to delve deeper discovers the complicated laboratories of the human machine for which there is no parallel. It is a coördination of units, it is built like a machine, but it has the organisation of an army. Yet again I say there is some advantage in thinking mechanically, if only to appreciate the value of keeping the machine clean, of preventing unnecessary friction of the bearings, of avoiding overloading or overheating, and of attempting to select the type of machine for the work required.

Advantages and Drawbacks of the Living Machine.

The living machine must work at certain disadvantages. Given the proper rate, proper load and proper lubrication, one hour in the day is as good as another for the non-living machine. Man is a diurnal, not a nocturnal animal; and furthermore a motor, save by gross misuse, does not necessarily become tired; fatigue of living tissue is, of course, inevitable. In this respect let us return to seek some more elementary analogies. The human machine enjoys the advantage that it does not wear out in the fashion common to ordinary machinery. On the contrary, it is constantly renewed, and so far from depreciation, improves with use for a number of years, until the only really perishable part, the magneto, wears out. Even if the paint becomes scratched—blisters on the feet—the paint is gradually restored spontaneously, without trouble or expense, to its pristine excellence.

Yet again one is tempted to further, perhaps dangerous, analogies. It was amusing and interesting to witness during the "Veterans' Rally" on the Brighton-road the spectacle of a 30-year-old puffing and wheezing its way along, not a single part of it without a defect of some kind, but still proceeding under its own power. It passed by the roadside a magnificent £3000 modern representative, temporarily immobilised, in all its pride and perfection, by some such trifle as a loose electrical connexion, or a tiny piece of grit in the carburetter jet. So, I reflected, it is with the human machine. We see a body in the last stages of a mortal illness in which practically every organ is the seat of disease and more or less impaired function, but in which life continues with an intelligence completely unclouded. With this we contrast the man in rude health, suddenly smitten down by a clot in a vessel supplying a vital area, or some other trifle almost ludicrous in its terrible capacity for turning life into death. Some years ago a man was brought into this hospital dead. Examination and inquiry into antecedent circumstances revealed the following. In leaving a public-house he injured his hand in the swinging door. Instinctively he applied his mouth to the injured part and inhaled a small piece of skin which had been abraded straight into his larynx with the production of spasm of the vocal cords and death. The history of medicine is full of examples of the most trivial injuries being responsible for sudden heart failure. Unfortunately, analogy breaks down at this stage; the motor-car may be restarted; life, once arrested, is arrested for ever.

"*A Fat Spark.*"

Apart from loss of power through physical causes identical with those which may affect the petrol engine, the human machine has the additional disadvantage that the magneto may, through purely emotional causes, fail spontaneously to work efficiently and provide a "fat spark." Such functional consequences, no matter upon what they must ultimately depend, to a great extent determine human efficiency. In motoring terms, a soiled magneto or missing plug; in medical language, brain fag or neurasthenia. Much may be said in admiration of the perfect timing mechanism which in a motor-car arranges the opening of the inlet valve and the closure at the precise moment when the compression stroke is completed with the remarkable rapidity necessary for great velocities. And yet what is such a mechanism compared with the human machine? When walking four miles an hour, only half a second elapses from the time the heel is raised until the limb has swung forward and the foot is again planted on the ground. Yet in that half second, 54 muscular engines have been started and stopped, speeded up, and slowed down a countless number of times. And this is the merest trifle compared with the performance of a crack high jumper. Think of the mechanism controlling the complexity comprised in such a series of directions as these. "The left foot is brought up level with the bar; the right leg is kicked out towards the right and is then cut in under the left leg, whilst the jumper should then give his hips a wriggle upwards, completing the movement by kicking the right heel up behind the body and swinging the left arm over and down." And the time during which the entire series of coördinated movements is completed is four-fifths of a second!

Selection for Special Purposes.

A feature of practical importance which frequently comes up for discussion is the ability to recognise types which are suitable for particular purposes, a criterion which would be of overwhelming importance in all branches of human activity. We know that many human machines are clearly unsuited for the vocation to which they have been committed through tradition, sentiment, caprice, necessity, and so on. But again it is necessary to limit oneself strictly to the physical side, and apply oneself first of all to the principle of the motor-car receiving its periodical overhaul, a principle which is reproduced in the occasional recommendation that a medical examination at intervals is a precaution which may prevent premature breakdowns. The underlying idea is good enough, no doubt. The engineer oils and greases and cleans and so provides for absence of friction in any of the moving parts. He tightens all loose bolts and nuts, and replaces all defective parts by spares. Should there be a lack of power, he will locate the seat of the trouble, and remedy a defective magneto and its connexions, arrange a more suitable mixture for the engine, or loosen a binding brake. To a certain extent the doctor can offer analogies both as regards diagnosis and treatment, but his difficulties are increased by the complexity of diagnosis and the impossibility of replacing defective parts by spares. It is fortunate that Nature carries her own spares and automatically replaces worn-out parts until the mechanism itself wears out, when senility begins.

A binding brake may have its equivalent in the relative deficiency or excess of one of the ductless glands; though when lack of power sets in, the identification of the part responsible is complicated by the occurrence in human machinery of the functional disorders to which I have already referred, disorders which are unaccompanied by organic change and give rise, as we say, to no physical signs, but may be responsible for symptoms equal in magnitude to anything produced by serious disease. Perhaps in this connexion the only approach to mechanical analogy would be the introduction of a super magneto specialist.

It is conceivable that such a periodical examination might reveal to the trained eye some superficial manifestation of an apparently innocent character, in reality a very early appearance of a serious disease. But as regards internal disorders and serious constitutional disturbances, these do not necessarily advertise themselves externally nor by symptoms any more than grave internal trouble in the petrol engine which, however imminent, may be quite unsuspected until the bearing seizes or the shaft breaks.

I cannot help thinking that the man who wants to subject himself to regular examination is the equivalent of the fussy owner-driver, who wants to take excessive care of his car and is perpetually taking the engine down to discover the origin of some supposed abnormality, or even to reassure himself that all is well. And exaggerated caution must surely lead to morbid imaginative notions equivalent to keeping the car in the garage instead of on the road.

Super-Performance.

One witnesses many attempts to explain the capacity of the super-athlete. The possession of a special and sometimes peculiar proportion of the limbs or of a distinct musculature or even quality of muscle tissue is sometimes invoked. These are obvious explanations, and have a limited application. In our analogy with the petrol engine they would refer to the size of wheels and the gear ratios. As would be expected, a multitude of hypotheses are built up on dietetic considerations, and if a great athlete happens to have some queer prejudice in that respect, it is not surprising that he has a large following, and equally not surprising that the disappointments of his imitators are numerous.

The existence of a "wonderful heart" is sometimes proclaimed, always by an authority who has not the responsibility of showing in what respects the heart differs from that of thousands of other very ordinary athletes. The real explanation is simply that everything necessary in the construction of the machine is just right at the right time. And, after all, the difference which makes all the difference where super-performances are concerned is exceedingly small. Two-fifths of a second separates a great sprinter from the good sprinter, a difference of only 4 per cent. In intensive competition, 1/100th second is a determining factor; about four inches at the end of a race, and here one is in the region of only 0·1 per cent.

It would be far different if one were confronted with a man who would on present standards be in the class not of superman but superhuman. The appearance, let us say, of one who could run not 5 per cent. but 30 per cent. faster than anyone in history, or of one who could cover in an hour not 12 miles but 15 miles, or who could jump not 6 feet 8 inches, but 8 feet. We should then be compelled to look for some really special feature, either a peculiarity of muscle substance or an entirely strange biochemistry. But until that phenomenon arrives there is no need to seek the mysterious or fantastic.

So far as investigations into the physiology of the subject lead us, A. V. Hill says that velocity is not a question of exerting greater propulsive power but of low viscosity—i.e., lessened internal friction—of muscle. Endurance he has explained as dependent upon oxygen-supply and the capacity to tolerate fatigue products. As Hill puts it, the oxygen inspired during effort is income, and upon income no athlete can live. The lactic acid accumulating in the muscles as the result of insufficient oxygen income is the security for the oxygen debt—i.e., the oxygen subsequently used for oxidation. And so long as the security remains adequate, by so much may the expenditure of oxygen exceed income.

From these considerations we see that the natural capacity for exertion depends upon a number of factors. The oxygen income must be high—i.e., the heart and circulation generally and lungs are of the highest efficiency. The oxygen requirement must be economical—i.e., not extravagant nor wasteful through purposeless movements. The security for incurring a large oxygen debt must be good, and this is a factor inherent in the muscular fibre itself, but capable of improvement by training. And all of this seems delightfully simple in the laboratory. It will explain capacity up to a certain point; it will not explain some extraordinary discrepancies. For what no considerations of machinery, of chemistry, or of physics can explain is the will power and what is bound up with it, the reserve which is beyond measurement.

It is impracticable to perform experiments upon men in circumstances of extreme stress; and what cannot be measured is the willingness to submit to complete exhaustion, willingness which must vary in the same individual on different occasions and be influenced by a large variety of factors so that on one occasion he is prepared to fill the unforgiving minute with 60 seconds worth of distance run and on another his form is surprisingly bad.

We may congratulate ourselves that the efficiency of human machinery is not an affair of measurements only, not merely the determination of a maximum oxygen-supply. For if it were, competition would be a very dull proceeding, a mere question of preliminary calculation and decision by arbitration; and life would lose not a little of the spirit of adventure.

HOSPITAL COÖRDINATION AT CHESTER.—A consultative committee composed of representatives of the city council, Chester Royal Infirmary, Chester Maternity Hospital, and the Chester Division of the British Medical Association has been formed to consider the best means of coördinating the health work, municipal and voluntary, of the city.

MANCHESTER VICTORIA MEMORIAL JEWISH HOSPITAL.—It is proposed to extend this hospital at a cost of between £20,000 and £30,000. Adjoining land has been presented upon which a new block will be built to comprise a children's ward, complete medical and surgical units with an X ray wing. It is claimed that this wing will have better accommodation, in the way of treatment, examination, and dressing rooms than any other hospital in Manchester. There will be an increase of 20 beds or, if means permit of providing accommodation for paying patients, of 36 beds. The annual report shows that for the year ending June 30th, 1929, there was an excess of expenditure over income of £3347, which brings the total deficit to £7000.

TREATMENT OF LUPUS ERYTHEMATOSUS WITH BISMUTH.

By R. M. B. MACKENNA, M.A. Camb.,
M.R.C.P. Lond.,

HON. DERMATOLOGIST, LIVERPOOL STANLEY HOSPITAL; HON. ASSISTANT DERMATOLOGIST, LIVERPOOL CANCER AND SKIN HOSPITAL.

Lupus erythematosus was probably first recognised as a definite clinical entity by Rayer[1] in 1827. Biette,[2] in 1828, gave a very graphic description of the general appearance of the disease. Hebra, in 1845, suggested the name "seborrhœa congestiva," and six years later Cazenave,[3] in a classical contribution to medical literature, gave the disease its present name. Since that date various eminent medical men, including Vidal, Feulard, Capelle, Leloir, Besnier, Brocq, Darier, Unna, and Leredde have studied the condition, and it is interesting to note, in view of recent contributions to the literature concerning this disease, that the majority of the early writers published their work in Parisian journals.

Since 1851 the term "lupus erythematosus" has signified an inflammatory disease which causes atrophy of the skin without ulceration. There are three definite clinical types of the chronic form of this disease: (*a*) In type 1 the lesions are slightly erythematous, and their surface is covered with fine scales. (*b*) Type 2 exhibits but a slight degree of erythema. Scaling is not a marked characteristic, but the orifices of the sebaceous and sweat glands are blocked with plugs of horny cells. The areas affected are more indurated and less pliable than those of the first variety. (*c*) In type 3 the lesions are vividly erythematous, and there is but little scaling. The incidence of the first two types of the disease is approximately equal. The third type of the disease is rarely seen, and in my experience is more commonly found in females than in males.

The cause of lupus erythematosus is unknown, but it is commonly presumed that the condition is a localised manifestation of a chronic toxæmia, the source of the toxins being the usual foci in the teeth, tonsils, nasal sinuses, and intestines. Some authorities still consider that the disease is a tuberculide. No theory of importance as to why there should be at least three chronic forms of the disease has yet been advanced.

In 1911 Sequeira[4] wrote:—

> "Very few skin affections are more difficult to treat than lupus erythematosus, and a favourable prognosis can never be given, even if the disease has only attacked a small area. All that can be promised the patient is that eventually, perhaps after years, there may be a gradual remission of the symptoms and scarring of the affected areas."

It is still advisable to give a guarded prognosis, but the outlook has been improved by the addition of two new remedies to our armamentarium during the last ten years. The first is injection of gold salts,—e.g., sanocrysin and krysolgan. Good results are claimed for the injection of these, but they are extremely toxic, and cannot be used as routine measures. The second is by the injection of bismuth or its salts.

History of Bismuth Treatment.

In January, 1929, three Frenchmen, Nicolas, Lacassagne, and Rousset[5] published the first detailed paper on the Treatment of Lupus Erythematosus by Injections of Bismuth Salts. They pointed out that there had been several isolated observations on the treatment of this disease with bismuth by Hudelo and Rabut,[6] Lortat-Jacob and Legrain.[7] The earliest of these observations was not published in November, 1926, but the investigators were not very satisfied with their results, as Lortat-Jacob reports:—

> "The experience which I have of bismuth treatment in the cure of lupus erythematosus shows that the cure is sometimes, but only in exceptional instances, obtained. Sometimes there is a transitory amelioration, but the majority of cases remain indifferent to anti-syphilitic treatment."

On June 9th, 1927, Sézary and Benoist[8] communicated two cases to the Société de Dermatologie, and shortly afterwards Nicolas and his colleagues commenced their investigations. In their paper published in January, 1929, they state:—

> "We estimate that the value of bismuth in this disease is greater than has yet been suggested. If all our patients have not attained a complete cure, the rapidity with which the signs have receded, the immediate effect on the subjective symptoms, and the state of the integument after a cure has been obtained, all militate in its favour."

Of 17 cases which they publish, all improved under treatment and ten were apparently cured. Hydroxide of bismuth was the preparation used in the majority of cases.

A Series of Twenty-four Cases.

During the last nine months I have treated 24 cases of chronic lupus erythematosus with bismuth injections. Metallic bismuth, bismuth oxychloride, and sodium-bismuth-thio-glycollate, have been used, the injections being given deep-subcutaneously or intramuscularly. Whenever possible the injections have been given once weekly or fortnightly, and in the majority of the cases after every 10 or 12 injections a period of some six weeks has been allowed to elapse before continuing bismuth treatment, so that there should be no risk of poisoning due to a cumulative effect. With regard to dosage, the average adult male or female can tolerate a dose of 0·3–0·4 g. of metallic bismuth or oxychloride of bismuth per injection, but 0·4 g. is the maximum which can be employed with safety. In the majority of the cases quoted below 0·4 g. of the metal or its salt has been given at each injection. I have found that metallic bismuth and bismuth oxychloride have approximately an equal therapeutic effect, whilst the thio-glycollate, which is a water-soluble bismuth salt, and therefore enables one to obtain a higher concentration of bismuth for a short period, has not, in my hands, given better results than the other preparations. I have tentatively tried giving bismuth oxycarbonate and bismuth salicylate in doses of grs. 5 to 10 thrice daily by the mouth, but without any apparent advantage to the patients. Inunction with colloidal bismuth preparations has not been tried, but local applications of "suspensol" (which is a colloidal preparation of metallic bismuth in an ointment basis) have not given satisfactory results. Two cases were given a 5 per cent. colloidal bismuth oxychloride ointment, and in one case (No. 12) there was a marked improvement.

Of a total of 24 cases treated since March, 1929, the following is a brief record of 14 of the most typical cases:—

Cases of Type 1.

Case 1.—Miss A., aged 28. First seen Feb. 18th, 1929. Four small areas of lupus erythematosus in scalp; three on forehead (two years' history). From May 14th to Nov. 30th a total of 5·6 g. metallic bismuth were given by injection. Considerable improvement occurred. Only two affected areas in scalp remain.

Case 2.—Miss G., aged 36. First seen May, 1928, when she stated that she had suffered from lupus erythematosus for 11 months. The nose was affected and there were symmetrical patches in front of the ears. From March 28th to Nov. 7th a total of 3·2 g. bismuth were given intramuscularly, the injections being given at irregular intervals. On Nov. 30th the patient was apparently cured.

Case 2.—Miss B. M., aged 18. Many small discoid areas of lupus erythematosus on scalp. A few on forehead. Lesions also on hands. From May 2nd to July 11th, 1929, a total of 0·8 g. metallic bismuth was given by injection. There was marked improvement, and from August 8th to Sept. 5th a total of 1 g. bismuth oxychloride was given. The lesions on the hands and forehead disappeared, but those on the scalp remained. From Sept. 17th to Oct. 17th 0·8 g. bismuth oxychloride was administered. On Oct. 30th one new area on the scalp was noticed. Two injections, each of 0·3 g. bismuth oxychloride, were given during November, but these had no apparent effect. Ung. bismuth oxychloride 5 per cent. was then prescribed. The patient has not returned for further treatment.

CASE 4.—Mrs. M., aged 38. *Lupus erythematosus of nose.* From August to November, 1929, a total of 4·8 g. bismuth oxychloride were given by injections. The lesions rapidly healed and there has been no recurrence.

CASE 5.—Miss B., aged 28. Nose affected and several areas on the cheeks. From August 2nd to Nov. 22nd a total of 2·7 g. bismuth oxychloride and 2·4 g. metallic bismuth were given. Considerable improvement has occurred, but none of the lesions have entirely disappeared.

Cases of Type 2.

CASE 6.—Mr. P., aged 39. First seen in July, 1929. Disease had been present for four years. On one occasion the lesions had been painted with acid nitrate of mercury, but for the preceding year nothing, except ung. acidi salicyl., had been used. The disease had steadily progressed, and in July, 1927, there was one large area on the left cheek and six small areas, each the size of a florin, affecting the left side of neck, nose, right cheek, and the left ear. From July 1st to August 8th a total of 2·6 g. metallic bismuth were administered. From August 21st to Sept. 13th 0·8 g. of thio-bismol was given, but there was no definite improvement. 1·4 g. metallic bismuth were administered during October, and the condition improved considerably. The patches are now healing at the periphery, but none of the original areas has completely disappeared.

CASE 7.—Mrs. O., aged 35. Oval patch of lupus erythematosus on nose, 2¼ in. in longest diameter. From July 10th to August 15th, a total of 0·6 g. metallic bismuth and 0·3 bismuth oxychloride was given. The lesions reacted rapidly to treatment, and by August 31st a cure had apparently been obtained.

CASE 8.—Miss H., aged 31. One discoid area of lupus erythematosus the size of a shilling on left cheek. One area the size of sixpence on forehead; 17 months' duration. From April 25th to Sept. 10th 1·8 g. metallic bismuth were given, and the patient was then discharged as cured.

CASE 9.—Mr. G., aged 38. Lupus erythematosus of two years' duration. Three discoid areas the size of a florin on left cheek. One area on neck below right ear. From July 16th to Nov. 30th 2·8 g. bismuth oxychloride were given. Lesions commenced to clear up rapidly.

CASE 10.—Mrs. F., aged 35. Lupus erythematosus. Three years' history. One discoid lesion on left cheek. From August 13th to August 26th 1 g. metallic bismuth and 0·2 g. thio-glycolate given. On August 17th carbon dioxide snow was applied. On Oct 15th she wrote "I am not cured."

CASE 11.—Miss G., aged 25. Very severe lupus erythematosus affecting the whole of both cheeks, the nose, and forehead, with a few discoid lesions in the scalp. From July, 1927, to April, 1929, she had received much local treatment with ultra-violet light. Salicin had been administered internally, and numerous external applications had been prescribed. From April 13th to Dec. 7th she received 4·8 g. bismuth and 1·5 g. bismuth oxychloride. Great improvement took place during October and November. Healthy skin is now visible in many areas on the cheek and forehead, and within the next six weeks she should be completely cured.

CASE 12.—Mr. H. L., aged 42. Two discoid lesions, the size of a florin, on each cheek, and one on left side of neck. From September to November, 1929, 4·8 g. bismuth were administered, and a great improvement was noticed.

Case of Type 3.

CASE 13.—Miss M., aged 34. Lupus erythematosus affecting eyelids and nose, extending downwards over the cheeks to a distance of one inch from the eyes. From July to October, 1929, a total of 4·8 g. metallic bismuth were given. No improvement. From November to December 1·6 g. oxychloride bismuth given. Some slight improvement then occurred, and the edges of the lesions began to clear up. No marked improvement was noticed until Dec. 4th. The patient was given 5 per cent. ung. bismuth oxychloride, and considerable improvement occurred during the ensuing 14 days.

CASE 14.—Miss C. M. J., aged 34. Lupus erythematosus of hands. Duration unknown. From April 10th to Dec. 7th a total of 1·4 g. metallic bismuth were given. Considerable improvement resulted.

With regard to local applications, in so far as was possible, the patients were kept on the same treatment as had been previously prescribed. The cases of types 1 and 3 usually used lotio calaminæ with 1 per cent. ichthyol, or Lassar's paste. The cases in group 2 usually applied 2 per cent. ung. acidi salicyl. Recently, local treatment with acid nitrate of mercury has been employed in a few cases, and recovery seems to be hastened by the adoption of this method in conjunction with bismuth therapy, although the amount of scarring is thereby increased.

Results.

To summarise these results. Of 14 cases of chronic lupus erythematosus—

5 cases, or approximately 36 per cent., were of type 1.
7 ,, ,, 50 ,, ,, 2.
1 case ,, 7 ,, was ,, 3.

In one case the hands alone were affected.

Two cases of type 1 and two cases of type 2 have been discharged as cured. Every case of the disease in groups 1 and 2 has improved to a greater or less extent, but the single case in group 3 only improved very slightly on bismuth injections. The time taken to establish a "cure," and the amount of bismuth which has to be administered, varies greatly with each individual. For example, Case 7 required only 0·6 g. bismuth and 0·3 g. bismuth oxychloride to obtain an apparent cure, whereas Case 12 was not cured after receiving 4·8 g. bismuth.

The one outstanding fact is that every case which has been treated with injections of bismuth, or bismuth salts, has improved, and has improved more rapidly than would have been anticipated had other remedies been employed. One other satisfactory finding has been that the lesions which respond to bismuth treatment heal with a minimum of scar formation, and in several cases, notably those belonging to type 2, healing has taken place without any residual scar being formed.

The mode of action of bismuth in lupus erythematosus is extremely hypothetical. The metal may act as a detoxicant, either in the tissues or when excreted into the large gut. It may perhaps act as a bactericide. If as a detoxicant it probably does not exert any influence when excreted into the bowel, for bismuth by the mouth has no marked therapeutic effect in these cases. More probably it acts by inhibiting the reaction of the tissues to the toxins (or bacteria) which cause the disease. Anwyl-Davies,[9] in a monograph on the use of bismuth in the treatment of syphilis, quotes the experiments of Kolle and Evers,[10] who injected a suspension of bismuth subcutaneously into the ears of rabbits, and four weeks later inoculated the animal with *Spirochæta pallida*:—

> "No primary lesion or generalised syphilitic infection occurred until the bismuth deposit was removed two or three months later by amputation of the ears. When this was done typical chancres developed, and the usual train of syphilitic signs ensued without a fresh spirochætal inoculation. Then they showed that in rabbits which had been inoculated with *S. pallida*, but in which no chancre had developed owing to the presence of the depôt of bismuth, the popliteal lymph glands contained *S. pallida*. Thus, this organism had not been prevented by the bismuth from travelling into the tissues. They made an emulsion from the popliteal lymphatic glands of rabbits in which the syphilitic infection had not developed owing to the presence of bismuth deposit, and demonstrated that other animals could be infected by inoculating them with this emulsion from an apparently immune rabbit (which had been inoculated with the lymphatic gland emulsion from another apparently immune rabbit which had not reacted to inoculation owing to the bismuth deposit).
>
> "Thus, the popliteal lymphatic glands of such apparently resistant rabbits are infectious, and it seems as though the bismuth in some way—possibly by some tissue reaction—merely *inhibits* the disease instead of having a direct curative action on the infection."

The tentative suggestion may therefore be made that any improvement occurring in a case of lupus erythematosus after the injection of bismuth or bismuth salts is due to the property which bismuth possesses in preventing the tissues from reacting normally to the toxins (or bacteria) which cause the symptoms of the disease. One would therefore expect that the persons who have been apparently cured will sooner or later exhibit a recurrence of the lesions. We may, however, claim that injection

Clinical and Laboratory Notes.

A CASE OF TYPHOID FEVER

WITH PERSISTENT NEGATIVE WIDAL REACTION BUT POSITIVE "O" AGGLUTINATION.

BY A. D. GARDNER, D.M.OXF., F.R.C.S.ENG.,
F. G. HOBSON, D.S.O., D.M.OXF., M.R.C.P.LOND.,
AND G. STENHOUSE, M.B., CH.B.MANCH.

THE notes of the following case, which has features of interest both for clinicians and pathologists, are published with the aim of calling attention to an important recent advance in laboratory methods, whereby cases of typhoid fever with persistent negative Widal reaction can be serologically diagnosed.

Clinical Description.

Miss A. B., aged 28, went to Italy for a holiday on August 14th, 1929. On Sept. 2nd, after bathing in a hot sun, she developed a headache and an acute attack of diarrhœa. Still suffering from headache, drowsiness, and increasing anorexia, she returned to England on Sept. 4th, and on the 13th had to take to her bed. She was first seen by one of us (G. S.) on the 14th. On the 19th, 17 days from the first sympton, a Widal reaction, done at the Royal Berkshire Hospital, Reading, was negative. She had never been inoculated against typhoid or paratyphoid fever. On the 25th a second Widal reaction, done at the Radcliffe Infirmary, Oxford, was negative. An examination of stools and urine was also negative for the typhoid group. A blood culture, however, yielded a bacillus, to be described below, which eventually proved to be *B. typhosus*.

The general clinical picture throughout the illness was of a severe typhoid fever, the first spots being detected on the abdomen in the third week. The spleen was never palpable, though splenic dullness was increased to percussion. During the fifth and sixth weeks there was a fairly severe hæmorrhage from the bowel. The sixth, seventh, and eighth weeks were complicated by a troublesome *B. coli* cystitis, and during the eighth and ninth weeks there was some periostitis of both femora. All complications were successfully overcome, and the patient made an uneventful convalescence. On Oct. 16th, 43 days after the first symptom, the serum still gave a negative Widal reaction to ordinary typhoid cultures. Two examinations of stools and urine for *B. typhosus* during convalescence were negative.

Bacteriological Notes.

The negative Widal test done on Sept. 25th at the Radcliffe Infirmary, Oxford (Dr. A. G. Gibson), with a standardised suspension of *B. typhosus*, was repeated and confirmed at the School of Pathology; and at the same time the serum was tested with two "O" suspensions of *B. typhosus*—viz., one made by treating with alcohol a smooth motile culture of *B. typhosus* 901; the other by adding 0·2 per cent. of formalin to a broth culture of the same strain in the non-motile "O" state. Granular agglutination occurred with both suspensions in four hours at 52° C., up to 1 in 125 (8 standard "O" units). This reaction was reported as positive though weak.

On the same day the Radcliffe Infirmary isolated from the patient's blood a non-motile non-lactose-fermenting bacillus of the typhoid coli group, which was not agglutinated by stock *B. typhosus* serum. Identification would therefore have been delayed had not an "O" agglutinating serum been available. With this, a full-titre "O" granular agglutination was obtained in a live saline suspension of the bacillus grown on an agar slope sown direct from the blood culture. The vast majority of the bacilli in the suspension were non-motile, but a very few swimmers were seen in the condensation water of the slope. Ordinary *B. typhosus* serum gave no flocculation (H) with this suspension, but slowly produced "O" granulation to a relatively low titre. Fermentation tests gave, on the following day, the picture of *B. typhosus*, and the bacilli in the various fluids were found to have acquired motility and agglutinability by ordinary typhoid (H) serum. The bacillus was clearly in the "O" state in the blood culture and first subculture, but rapidly changed to "H."

Further tests with the patient's serum gave granular agglutination (*a*) to 1 in 250 with a formolised broth suspension ("standard culture") of *B. enterit. Gärtner*; (*b*) to 1 in 500 with living saline suspensions of *B. typhosus* 901 H and O; (*c*) to 1 in 1000 with patient's own bacillus. Here the clumping was exceptionally fine; indeed hardly visible with the naked eye.

A repetition of the agglutination tests with a fresh sample of serum 20 days later gave: (*a*) again no H agglutination; (*b*) granular agglutination to 1 in 50 with formolised broth "O" suspension (6 standard "O" units); (*c*) granulation to 1 in 125 with living saline "H" 901; (*d*) feeble and unsatisfactory granulation to 1 in 125 with living saline "O" 901. It may be mentioned that the greater agglutinability of living suspensions is of doubtful value, since it raises the level of agglutination in normal serum as much as it increases the apparent titre of specific serum.

Commentary.

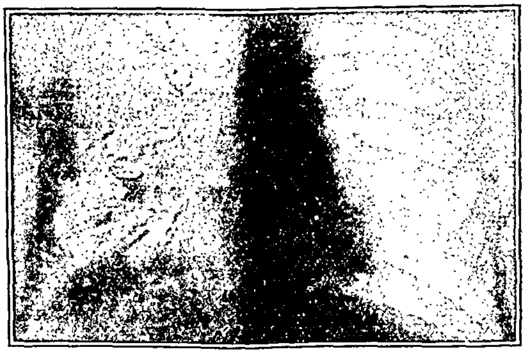
This case is far from standing alone. A considerable number of similar cases have been recorded by Burnet, Felix, and others.[1] We have heard very recently of another in this country, and a third came into the hands of one of us just before these notes were sent to press. [Negative H, positive O agglutination; non-motile "O" *B. typhosus* in blood.] In fact they are probably a good deal commoner than we have hitherto supposed. The value of the "O" test is, moreover, not confined to such cases as these or to cases in which O agglutination appears earlier than H; but it seems to be particularly great in the diagnosis of typhoid fever in inoculated persons with residual "H" agglutinins.

Since typhoid cases with negative "H" but positive "O" agglutination occur from time to time, clinicians should require, and pathologists perform, the Widal test with "O" suspensions in addition to the customary "H." Agglutinating serum of the "O" type should also be at hand for the identification of the so-called inagglutinable typhoid bacilli. The persistent low titre of the "O" agglutinins in this case is of interest.

BRONCHIECTASIS: FORME HÉMOPTOÏQUE SÈCHE.

BY L. S. T. BURRELL, M.D. CAMB., F.R.C.P. LOND.,
PHYSICIAN TO ROYAL FREE HOSPITAL AND BROMPTON HOSPITAL FOR CONSUMPTION;
AND
R. R. TRAIL, M.D. CAMB., M.R.C.P. LOND.,
MEDICAL SUPERINTENDENT, KING EDWARD SANATORIUM, MIDHURST.

THIS form of bronchiectasis is characterised by periodic attacks of hæmoptysis but absence of symptoms between the attacks. Since the introduction of lipiodol, bronchiectasis may be diagnosed in cases where otherwise it would have been completely unsuspected. Such cases are by no means uncommon and the following may be taken as a typical example.



Bronchiectasis shown by an injection of lipiodol.

A young man, aged 23, had always had good health and led a normal athletic life. He had just passed through a theological college, and was considered to be quite fit, when suddenly in August he had a large hæmoptysis of over a pint. There were no physical signs and he felt perfectly well afterwards, but he was sent to Midhurst Sanatorium. *Occasionally a few moist sounds were heard at the base of* the right lung, but these were not always present, and X ray examination showed no definite disease in the lungs. There was no cough or sputum and he suffered from no dyspnœa or fatigue. The fingers were not clubbed. On injecting lipiodol, however, a considerable degree of bronchiectasis was shown, as can be seen in the accompanying skiagram which was taken by Dr. Stanley Melville.

---

[1] See A System of Bacteriology, Medical Research Council, 1929, vol. iv.

In the absence of any symptoms no definite treatment was advocated, and the patient's health has so far remained good.

A NOTE ON THE USE OF AN

ORGANIC SULPHUR COMPOUND IN COCCAL INFECTIONS.

By Dr. Elie Sassoon
(ALEXANDRIA).

The following notes are taken from a record of cases of pneumococcal, streptococcal, and staphylococcal infections, treated during eight years' service in the Sudan as medical officer, with a new sulphur organic compound to which I have given the name of "sulphoserum."

Preparation of the Serum.—To 20 c.cm. of sterile normal horse serum is added 0·4 c.cm. of 2 per cent. sol. calc. sulphurat., the mixture hermetically sealed in ampoules, *and kept in an ice-chest. A reaction takes place within the* ampoules, by which the calcium sulphide is decomposed into precipitated lime, with liberation of SH_2—part of which is dissolved in the serum.

Method of Administration.—Sulphoserum may be given in two different ways: (1) By local application. The region selected is cleansed, the skin is scarified, and a pad of cotton-wool soaked with the serum is applied. The SH_2 absorbed produces a tingling sensation radiating from the point of application; when it causes vertigo the application is stopped. A slight rise of temperature with discomfort and headache sometimes occurs a few hours later. The application may also be made to wounds. Some cases are more sensitive than others; the treatment in any case is adapted to the extent of the scarified surface, and the quantity and time of sulphoserum applied.

(2) The intravenous method is used when the patient does not react to local application. The initial dose is 0·25 c.cm. *daily, increased if necessary. The injection should be given* very slowly.

Sulphoserum was found to be of value in all pneumococcal, staphylococcal, and streptococcal infections. If given in the early stage of lobar pneumonia the pain ceases and fever drops to normal on the second or third day. Given early in acute inflammations, such as cellulitis or sympathetic ophthalmia, pain and redness subside, and the temperature falls. I have also used the serum to prevent secondary infection after surgical operations.

Medical Societies.

ROYAL SOCIETY OF MEDICINE.

SECTION OF GYNÆCOLOGY AND OBSTETRICS.

At a meeting of this Section on Jan. 17th, with Dr. Arthur Giles, the President, in the chair, Dame Louise McIlroy described

Three Cases of Imperforate Vagina Occurring in One Family.

The first patient was a girl, aged 20, who had never menstruated, but who, for some time, had been complaining of monthly pain, and of swelling of the abdomen. On examination she was found to have an abdominal swelling extending to two inches above the pelvis, non-fluctuant, and rounded. Per vaginam, a bulging membrane was seen in place of the vaginal orifice. On operation a large quantity of menstrual material was released; the patient made a good recovery and afterwards menstruated normally. Subsequently a sister, aged 16, was seen, giving almost the same history, but in this case occasional vomiting had occurred. The abdominal swelling reached the umbilicus, and a smaller rounded swelling, clearly the uterus, could be felt at its apex. Operation again gave excellent results, the amount of fluid being "extremely large." On inquiry, a third sister, aged 14, was presented for examination, who also showed this condition, but without bulging of the membrane, and apparently without abdominal swelling. Operation, however, released two pints of menstrual fluid, and resulted in subsequent normal periods. Sections of the membranes by Prof. Geoffrey Hadfield showed a connective tissue stroma with blood-vessels and smooth muscle-fibres, and an outer layer of squamous epithelium.

Prof. J. Preston Maxwell said he had met this condition not infrequently in China, and that imperforate vagina could be diagnosed from imperforate hymen by the presence of the hymen as a small fold on the surface of the bulging membrane. He thought the cases described by Dame Louise were more likely to be imperforate hymen.—Mr. L. C. Rivett said that the interest of these cases lay in the fact that they had all occurred in one family. There had been no previous evidence of a familial tendency in this condition.—The Chairman described the difficulty of dealing with cases in which the vagina was represented by an uncanalised column of cells. On one of his patients, a girl of 16, he had had to perform an abdominal operation to establish a patent vagina.

Dame Louise McIlroy, in replying, asked what her cases should properly be called—imperforate vagina or imperforate hymen?—The Chairman replied that, as there appeared to be no traces of hymen visible on the face of the membrane, these were probably cases of imperforate hymen.

Mr. J. H. Hannan gave the results of investigations on the detection of

Anterior Lobe Hormone of the Pituitary in the Urine.

In 1922, he said, it had been demonstrated that the anterior lobe of the pituitary produced precocious sexual maturity in immature female mice, denoted by canalisation of the vagina, the appearance of œstrus as judged by the vaginal smear, and the presence of corpora hæmorrhagica in the ovaries. In 1928 Zondek and Aschheim had used the presence of anterior lobe hormone in the urine of pregnant women as a test for pregnancy. Their technique had been to use five mice weighing 6 g. each in every case. 1·2–2·4 c.cm. of urine had been injected into these animals in six portions, over a period of 48 hours. At the end of 52 hours the animals were killed and examined for signs of œstrus, for hæmorrhagic points in the ovaries, and for the formation of corpora lutea atretica in the ovaries as seen microscopically. Positive results in only one of the five was taken as evidence of pregnancy in the patient. These workers claimed 98 per cent. of accurate positive, and 99 per cent. of accurate negative results. Owing to the difficulties of obtaining enough mice, and the high mortality among them from toxicity of urine, Mr. Hannan had employed young rats, aged 6–8 weeks, in his experiments, only one animal being used for each case; 3 c.cm. of urine was given, all in one injection, and the rat was killed after 96 hours. All his patients had been cases of amenorrhœa from various causes, except for 15 normal non-pregnant women taken as controls. His results could be tabulated as follows:—

—	Cases.	Wrong.	Percentage error.
Pregnant women	41	3	7·3
Non-pregnant women ..	15	0	0
Diseased women, with amenorrhœa	43	12	27·9

He found that the reaction rapidly disappeared after delivery. In addition he had collected and analysed 913 cases from the literature with the following results:—

—	Cases.	Wrong.	Percentage error.
Pregnant women	452	8	1·8
Non-pregnant women ..	461	15	3·2

His own results differed from those of previous workers in having a higher percentage error among pregnant and diseased women, though he showed an absence of error among non-pregnant women. His error in the former cases could probably have been reduced by microscopic examination of the ovaries. Also the use of younger rats might give more trustworthy results. The test was positive only when fœtal elements were present in the patient. Some observers had found positive results in the case of hydatidiform mole, but he had not done so. In his opinion the test depended upon too many variable factors to be reliable; and if not reliable, it was of no great value.

Dr. **Veisner** (Vienna) said that during the last two years in Edinburgh he had helped to establish a pregnancy diagnosis centre based on this test. He did not consider it advisable to reduce the number of animals or to use rats. The anterior lobe of the pituitary produced four hormones, and during pregnancy two of these were also formed by the placenta and appeared in the urine. The test was, therefore, a placental sign. In cases where the production of hormone was too small to give a positive result the pregnancy usually ended in abortion. In their series the percentage error had been 3·02. Some of the negative cases had aborted, as might be theoretically expected.

Dr. E. M. **Robertson** said that at the Edinburgh centre, of the 400 cases confirmed by the doctors who sent up the specimens, the 3 per cent. of erroneous results could be analysed as follows:—

	Cases.
Unexplained by doctor	5
Evidence of dead fœtus	5
Endocrine disturbance. (Negative result, pregnant patient)	1
Two tests: first, positive; second, negative. (Possibly aborted during interval)	1
Hydatid, positive	4
Ectopic, positive	3
Tubal mole, negative. No villi seen microscopically	2

In two cases of chorion epithelioma positive results had been obtained, and also in one case of previous abortion, where curetting showed scanty fragments of villi still present.

Mr. F. **Dickens** said that among 250 cases of pregnant and non-pregnant women tested at the Middlesex Hospital he had found a 2 per cent. error among the pregnant and a 3 per cent. error among the non-pregnant cases.[1] The test had remained just positive as long as 24 hours after delivery. The larger error found by Dr. Hannan was probably due to the use of rats, in which animals spontaneous luteinisation was known to occur.

Dr. O. B. **Voge** mentioned the possibility of some chemical test being evolved, which would also throw light on the nature of the Zondek-Aschheim test. Working with bromine water on the lines of the histidine test, he had obtained 86 per cent. of results in agreement with the Zondek-Aschheim test, and on the same cases. If a number of cases of old urines were excluded, his results reached 91 per cent. of agreement.

Mr. H. **Burt-White** said that he had obtained 9 per cent. of errors in using the chemical test. He had found five out of six positive results in cases of exophthalmic goitre; diabetes mellitus, hæmophilia, and several cases of malignant disease had given positive results.

Mr. **Rivett** said that the test was of no value if the percentage error could not be reduced below Dr. Hannan's figure, for only one case in a hundred presented any difficulty in the clinical diagnosis of pregnancy.

The **Chairman**, in calling upon Dr. Hannan to reply, said that the test depended on the chorionic elements of the placenta; it was interesting that chorion epithelioma gave positive results. Chemical tests, if they could be made sufficiently accurate, would be extremely valuable.

Dr. **Hannan** agreed that the percentage error was too high, but repeated that his cases had been women with amenorrhœa; his findings in exophthalmic goitre had confirmed the chemical tests on the same cases. He doubted whether the error could be reduced below 10 per cent. while the test involved so many variable factors.

Prof. **Preston Maxwell** read a paper entitled

Further Studies on Osteomalacia.

In diagnosing osteomalacia, he said, deformity should not be remembered as the cardinal sign. There were other and much earlier signs and symptoms which were sufficient to establish a diagnosis, among which were pain in the back and thighs, spasm of the adductors, tenderness and softening of the bones, and muscle irritability. The disease was due to deficiency of vitamin D; or at least this was the case in China, in his opinion. It was observed that large numbers of girls were being brought into the province of Shansi during recent years, and in this province osteomalacia was particularly rife since the famine of 1875. It was probable that these girls were required to supply the places of those who died in childbirth as a result of the disease. In the late stages the deformities became marked, and the patient was liable to die of intercurrent disorders. In the early cases the gait was characteristic, with slight bending of the knees and adductor spasm. Scoliosis and kypho-scoliosis developed as the disease advanced, and a transverse sulcus appeared above the pelvis at the back. Radiography showed the characteristic tri-radiate pelvis, with the ischial tuberosities close together, sometimes associated with multiple fractures, and sometimes with marked bending of the long bones. The reason why fractures occurred in some cases and not in others was not understood; it possibly had something to do with the relation between blood phosphorus and blood calcium. The blood calcium was always low in these cases, but the diffusible calcium varied in its behaviour. In the chest the deformities were usually those associated with kypho-scoliosis; the pelvis showed rarefaction of the bones and rostration of the symphysis, with approximation of the ischial tuberosities. The sacrum became markedly convex, and the tip of the coccyx might approach so close to the ischial tuberosities that between them they obstructed the entrance to the vagina. The long bones showed bending and fracture, and the ribs on palpation revealed soft spots into which the finger sank. In pregnant women the fœtus was also affected; the cord blood calcium at birth might be down to 8 mg. per 100 c.cm. There was a tendency to antenatal rickets, and often the child developed rickets at the same time as the mother developed osteomalacia during lactation. The fœtus often showed marked irritability in utero. The food of these women consisted of corn bread, cabbage soup, rice, and vegetables; all cooking was performed with vegetable oils, and the diet contained no animal fat, meat, or eggs. The women lived indoors and took no exercise. When treated with fresh air, sunlight, cod-liver oil, and irradiated ergosterol, they usually improved enormously, mentally as well as physically. Spasm and pain of the muscles were definite symptoms of the disease, but the speaker was not satisfied that the tetany was a part of the disease at all. He thought that many mild cases of the condition passed undetected, even in this country, and that "funnel pelvis" was often a result of mild osteomalacia. Many cases of pain in the back during pregnancy improved on open-air treatment, full diet, and cod-liver oil. Osteomalacia of a marked degree could be cured by similar treatment, and irradiated ergosterol had proved of great value in this connexion; if cod-liver oil was given alone the doses must be very large—over ℥ii a day—but if ergosterol was given as well the dose could be much reduced. There was no excuse for oöphorectomy in these cases, and no evidence that it effected a cure. Operations for obstructed vagina by removal of part of the encroaching bones on one side were often very successful, and led to the renewal of marital relations and pregnancy, with subsequent delivery by Cæsarean section.

---

[1] See THE LANCET, Jan. 4th, p. 39.

Mr. RIVETT said that the treatment of osteomalacia opened a new field of activity for the workers in artificial sunlight and radium therapy, and fresh opportunities for investigation by the biochemists.—Dr. VEISNER said the condition might depend on two factors: lack of vitamin D, and lack of coördination in the endocrine apparatus to supply the conditions for its use. Probably both factors were involved.

Prof. EDWARD MELLANBY said that he was much interested by the evidence of fœtal rickets demonstrated by the radiograms of Prof. Maxwell. He had tried to produce this condition, using pregnant bitches, but without success, since by the time the calcium deficiency was marked enough for the purposes of the experiment the animals died. The results of absence of vitamin D from the diet were aggravated, in his opinion, by the high proportion of cereals taken. Cereals actually increased decalcification, as could be shown by giving oatmeal in rickets, to take an example. Tetany apparently bore no relation to total calcium or total phosphorus, but to some physical condition of the calcium.

Dr. HARRIETTE CHICK said there had been much osteomalacia of a minor degree in Vienna immediately after the late war. It was largely a disease of winter and occurred among the poorest classes; deformities were most marked in the convents, where fat was rare. Cod-liver oil had proved invaluable. Cases had been found among men as well as women. Possibly in China men were also affected in minor degree.

Dr. G. W. THEOBALD said that the disease did not occur in Malaya, Southern India, or Siam, but that cases were found in Northern India among the women who kept strict purdah and seldom saw the sun.

The CHAIRMAN said he was glad to hear Prof. Maxwell denounce oöphorectomy in these cases. The demonstration of the curability of the disease had been striking, but he would be interested to know whether it were not liable to recur on return to faulty conditions.

In replying, Prof. MAXWELL said that the only possible reason for removing the ovaries was that the operation stopped menstruation and pregnancy, and saved a little calcium by these means. It was an inexcusable form of treatment. Many men showed the disease in China. The condition recurred if the patient returned to unsuitable diet and surroundings, but the aim was to train them to avoid this while they were in hospital.

SECTION OF ELECTRO-THERAPEUTICS.

AT a meeting of this Section on Jan. 17th, with Dr. C. A. ROBINSON, the President, in the chair, a paper on

CUTTING CURRENTS

was read by Mr. JOHN ANDERSON (Dundee). These currents, he said, had not received the same attention in this country as in America. But he was sure that surgical diathermy had a wider application in treatment than was at present realised here. It was now 16 years since he had started a clinical investigation on the uses of the cutting current in the ordinary work of the general surgeon. His small Schall apparatus had proved until recently to be the most efficient cutting instrument he had ever tried; he had since tested ten other instruments which were reputed to cut well, but he had been continually disappointed in them. The Cushing-Bovie machine, however, which he had just begun to employ, had a wider range than any other, and he had reason to believe that healing would be equally good with it. Since 1923 he had used diathermy in 98 cases of radical removal of breast cancer, and primary union had been the rule; in only a small number was there delay in healing, or any difficulty in that respect. The group of cases so dealt with also had a shorter stay in hospital than those operated upon with the knife. When there had been some delay in union, it could usually be attributed to some technical inefficiency in the instrument, causing more coagulation and less cutting effect than was desirable, dehydration being consequently excessive. Electrical experts still differed about the exact nature of the various currents produced by the Schall machines. The frequency of the small Schall, as tested with the wireless, was probably over a million, and the waves were practically undamped in character. With the Cushing-Bovie machine the depth of dehydration could only be regulated by using different electrodes or by contact currents. The heavier the electrode the deeper the dehydration, and the more rapidly the active electrode was acting the lighter the dehydration. With this instrument it would now be possible to regulate accurately the amount of dehydration and the rapidity of cutting in the different tissues.

Mr. Anderson said he used the cutting current for all biopsies because he believed it eliminated the risk of spreading cancer cells. Even in cases in which radium was to be used he felt that one could complete the academic picture without increasing the risk to the patient. When the tumour was large he used circumvallation and then excision by the cutting current. When it was small, circumvallation was liable to interfere with the histological appearance of the section.

Results in Malignant Disease.

As regards results in his series of cases, he said he realised that no results of value could be given until at least eight years had elapsed; but up to the present only two of the 98 cases had shown local recurrence apart from a general carcinomatosis; there had been no case of secondary hæmorrhage, nor any instance of marked protein shock. Conversely, there had been much less post-operative pain and shock than with other methods. He thought the absence of post-operative pain after diathermy excision was due to "capping" of nerves after their section. In one case he did a radical excision of the breast at 4 P.M., and at 8 P.M. the patient was listening-in to the wireless. In inoperable cancer he used the coagulating rather than the cutting current. He employed the method for all tumours of the bladder, and cystoscopic control had proved that after its use the healing in this area was especially good. One could frequently see the operation wound when the knife had been used, but the diathermy excision wound often was not discernible. To bring about dilatation of the bladder it was important, in his opinion, to use air rather than water. After opening the abdominal wall one could then see exactly what one was doing, aided by the guidance of the finger. In prostatectomy, by the open operation according to Sir John Thomson-Walker, he had found the diathermy current a great advantage, as compared with suture or ligature, to produce hæmostasis. He had clamped vessels with forceps and simply applied the electrode to the forceps to bring about the local coagulation. He used diathermy for titivating the prostatic bed after ordinary prostatectomy, and he used it also for partial prostatectomy, and even for complete prostatectomy when the gland was small and hard. Further, he used it to make room for the insertion of radium in cases of malignant disease of the prostate; and in none of these prostatic cases had there been any alarming secondary hæmorrhage. For cancer of the tongue he had been employing both the coagulating and the cutting current. In the tongue cases a primary laryngotomy and packing of the nasopharynx were carried out before the tongue excision was done; this not only gave the anæsthetist a chance, but also prevented the aspiration of matter into the thorax. In a general way he was able to declare that this method had rendered the risk attendant on operative procedure almost negligible. Most of the patients were able to get up on the second or third day, and left the hospital within ten days. A number of tongue cases were thus dealt with which formerly were pronounced inoperable and were not touched. Diathermy was used, too, for skin, lip, and mouth tumours, hæmorrhoids, and tumours of the vulva, but he had not yet tried it for brain and abdominal tumours.

The method was criticised, said Mr. Anderson, because it was not bloodless. It was not intended to be so; but it reduced the loss of blood by half. Operation was bloodless when the coagulating current was used, but in that case it was unreasonable to expect primary healing. Two types of operation had, therefore, to be considered. When one was cutting through relatively safe tissue and attempting to prevent the manipulative spread of the cancer cell, the arc electrode with its 0·1 mm. dehydration was sufficient to prevent dissemination, for it sealed all lymphatic vessels and at the same time prevented capillary bleeding. A considerable number of cases had been reported in which healing was bad and some sloughing of the wound took place. He was familiar with those cases; they had been associated with a machine which was not working properly or with faulty technique; in other words, coagulation was too deep, and the dead tissue left was in too large quantity for the natural process of repair to overcome.

Future of the Method

It was interesting to inquire why the method was not more used. In this country there was considerable uncertainty about the exact nature of the currents, their effect on tissues, and the varieties of current produced by different machines. Satisfactory liaison was lacking between the electro-therapeutist, the surgeon, and the electrical expert who designed or built the machines. Some of his colleagues wished to establish the method in their clinics, but found a difficulty in procuring an efficient machine which would yield a uniform output. Until recently, with an alternating current he had not been able to get an efficient cutting effect. Until machines were properly standardised, diathermy for surgical purposes would not take the place in this country which it ought to have. The surgeon was not willing to hand over his material to the electro-therapeutist—for what he often considered might be experimental purposes—with the result that he might be using a machine which did not carry out the best work. In Europe very few machines had been produced which gave a first-class cutting current under control. He himself had enjoyed the close coöperation of Mr. G. H. S. Milne, and he thought that it was essential to work with a technician in this way. It might be possible to answer such questions as: What is a spark? What is its effect on tissue? Does it affect by electrical means the staining agents? What is the effect of the electrical current on the local anæsthetic which is impregnating the wound? He had been much disappointed with local anæsthesia in association with the use of the cutting current. Some patients complained of pain in such circumstances, and then resort to the knife eased the pain. In examining histological changes in the cells after the use of the diathermy current he would prefer to make a series of sections by immediate freezing, instead of by the prolonged hardening method.

The Cushing-Bovie machine, which Mr. Anderson demonstrated, seemed, he said, to be a long way ahead of any other he had tried. The amount of dehydration seemed to depend almost entirely on the nature of the damping of the wave; a purely undamped wave seemed to give almost the same effect as a scalpel. He had never used more than half of the possible power of this machine, and that was for sealing vessels. Most of the surgical work was done with 35 per cent. of the total power. Cartilage could be cut well with a high voltage. He had been able to cut out a shelf of an ox's femur with a simple wire snare, as if it had been cheese. For dealing with fat, a heavy dehydration was best. In conclusion, Mr. Anderson said that surgical diathermy would do all that the scalpel could do in the treatment of malignant disease, and had certain advantages over the scalpel. What was needed was a standard portable relatively cheap and relatively fool-proof apparatus. The present machine was not portable nor cheap, but the method was absolutely safe.

Discussion.

Mr. E. P. Cumberbatch said it was one of the functions of medical officers in charge of electro-therapeutical departments not only to administer electricity to such cases as were sent to them by the staff, but also to keep them in touch with new electrical methods. He had first seen this cutting method in the clinic of Howard Kelly, of Baltimore, and then he learned that the same means was being used by Mr. Gordon Taylor at the Middlesex Hospital. Afterwards he got to know that the latter learned the method from Mr. Anderson, of Dundee. He, Dr. Cumberbatch, implored every candid man who desired help for himself or his neighbour to make a thorough investigation of this method. At present the majority of surgeons in London were using radium in treating malignant disease, but surely there was a place here for the cutting current.

Dr. G. B. Batten urged that such team-work as had been mentioned should commence immediately; wireless was a good example of a demand producing in a very short time such investigation as had resulted in a great accession of knowledge.

Mr. H. P. Gough said he hoped to profit by Mr. Anderson's lecture in the designing of future apparatus. On behalf of Messrs. Watson and Sons he offered the best possible coöperation towards the attainment of perfection of apparatus.

Dr. J. B. Cook suggested that the apparatus had other uses in the profession than in operating for malignant disease. He asked whether it could not be used for operations on bone, as in removing portions in osteomyelitis. Perhaps it could be used for mastoid operations also, in which hæmorrhage was often a trouble.

Dr. C. G. Teale pointed out that in using the Schall machine it was important to keep the electrode in motion, otherwise a slough formed, and that interfered with rapid healing. At the hospital he was connected with, a surgeon who had been working with Dr. Harvey Cushing in America was anxious to use the method for dealing with cerebral tumours, but in preliminary experiments he found it difficult to keep the electrode moving quickly enough for this cerebral work.

Prof. Geoffrey Hadfield said he was a member of a team of the kind which the opener and several other speakers referred to, and that team had been carrying out a research, chiefly on animals, because working on dead meat did not afford information as to what happened in the tissues. What was needed now was a widespread propaganda among surgeons, who should learn what the method could accomplish; this would obviate poor results from coagulating currents, which inevitably delayed healing. The result so far was a bias in favour of the diathermy knife in comparison with the ordinary knife in the matter of recurrences after operation.

Mr. E. W. Riches, speaking as a former house surgeon to Mr. Gordon Taylor, said the sealing of the vessels by this method obviated the need for applying numerous ligatures. There was a danger that cartilage would necrose if touched with the diathermy knife.

Mr. Anderson, in reply, said he had only known this Cushing-Bovie machine for ten days. With the Schall apparatus it was necessary that the knife be kept moving, preferably with a movement as if making a rapid sketch. As soon as movement was slowed or stopped a coagulating effect occurred. With the Schall machine a pure cutting current was not used.

ROYAL SOCIETY OF TROPICAL MEDICINE AND HYGIENE.

A MEETING of this Society was held on Jan. 16th, the chair being taken by Dr. G. CARMICHAEL LOW, the President. Prof. MAX H. KUCZYNSKI (Berlin) read a paper by himself and Dr. BIANCA HOHENADEL on the

ÆTIOLOGY OF YELLOW FEVER,

with special reference to the problem of insect-borne disease. An abstract of this appears on p. 180.

The PRESIDENT sketched the chequered history of research into the ætiology of the yellow fever organism, and emphasised the caution which must be observed before coming to a conclusion.

Dr. J. A. ARKWRIGHT wished to know further details about the bacillus; how it was possible to distinguish it in culture from other diphtheroid bacilli, and whether it had an exotoxin which could be separated by filtration. He also inquired the criterion by which Prof. Kuczynski decided the presence of yellow fever in an animal, and suggested that Prof. Kuczynski's method was somewhat unnecessarily complicated. He understood that in typhus cultures which began as cocci changed to something which, if it was not exactly proteus X. 19, resembled it. This meant that bacteriologists were called upon to accept an entirely new idea, and one that required searching criticism. At the same time, proteus and rickettsia both had a fundamental relationship to typhus fever; the change must take place somewhere, and it was perhaps begging the question to criticise the change which was alleged to occur in vitro. It was necessary, however, to take care that one's faith in the unity of the two types of organism did not carry one away into accepting these extraordinary changes without question.

A Secondary Organism?

Prof. E. HINDLE proposed to criticise not the facts related by Prof. Kuczynski, but his interpretation of them. In the first place, it was true that in the normal course of events an animal infected with yellow fever had a fairly regular temperature chart. As a rule the temperature went down quickly, but by no means always; exceptional cases were constantly being reported of long incubation periods and long atypical fevers, with animals succumbing up to 23 days. From these atypical infections it was possible to recover typical infections, but as these atypical courses were usually reported in man, the results in animals should not be accentuated too much. The ordinary infection with a rise of temperature on the second or third day, and then two days afterwards a sudden drop and death, was strikingly different from the infection in which the rise lasted for seven or eight weeks. He himself, however, had seen incubation periods as long as 12 days, and the temperature charts should therefore not be regarded as indicating any important difference between infections with virus and infections with the bacillus. Assuming that an injection from a culture might contain a very dilute or attenuated virus, a fever or infection of this type might reasonably be expected.

A fact which might explain many of these results was that, in yellow fever, particularly, destruction of the liver was one of the important features of the disease. Work on ketosis had shown that when the liver was infected the animal became especially liable to infection with secondary organisms. Various species were particularly liable to various kinds of secondary organisms, and it was conceivable that a monkey infected with yellow fever might be infected fairly constantly by the same secondary organism. Secondary diphtheroid infection might therefore occur with a certain amount of regularity, although its connexion with the disease was only accidental. Mr. Hindle had been carrying out experiments to determine whether it was possible for the virus to be associated with bacilli; he thought there were some grounds for believing that it could. On broth and agar, both aerobically and anaerobically, the organism departed from the small form and became somewhat larger, more closely resembling Hoffmann's bacillus. If the bacillus were mixed with the virus by soaking in it for a day or two and then washing, virus would be absorbed. The bacillus itself would then produce no infection, but the washed bacillus would. Prof. Kuczynski, he supposed, injected an amount of virus approximately equivalent to 1,000,000 lethal doses, corresponding to a gramme of tissue or a cubic centimetre of blood. If subcultures were made, presumably a dilution was taking place from tube to tube, and by the sixth or seventh subculture there was practically no chance of any virus remaining. Assuming, however, that all the virus was concentrated in the bacilli, so far from diluting ten times when making a subculture, the amount of virus might be only halved, or reduced by even less. This would explain the achievement of positive results with subcultures up to the thirteenth or fourteenth passage.

It might be objected that the virus could not live so long. Actually, however, it would live in glycerin for months. The known properties of the yellow fever virus were very peculiar ones for a bacillus. On the one side was extraordinary resistance, and on the other fragility. It resisted glycerin and cytolytic agents, though it formed no spores. On the other hand, it was very susceptible to acidity, and died when the pH was lowered to about 4. All this evidence suggested that yellow fever was caused by a virus rather than by a bacillus of the kind suggested, which, if it resembled the diphtheroids, might be expected to resemble them in its physical properties.

With regard to sublethal doses: when the minimum lethal dose was approached, certain animals seemed to show infections without any obvious signs of disease. Mr. Hindle did not see why these infections by the bacilli should be of any particular consequence. It was not necessary to assume a bacillus different from the virus. The infection of an animal with monocytes from a recovered patient brought yellow fever into line with other virus diseases, and was an extremely important and interesting piece of work. So far, however, from providing evidence in favour of a bacterial causation, it favoured the virus theory. He supposed that the monocyte was the refuge of the residual virus which was so common in animals and patients who had recovered from yellow fever, and that the washing had simply removed the bodies which had prevented the latent infection from being shown in the previous experiments.

Further Criticism.

Prof. J. C. LEDINGHAM did not think that Prof. Kuczynski's evidence was at all convincing. He asked for definite information on whether the organism was capable of infecting a susceptible animal. He had gathered that the virulence of the organism was highly capricious. If that were so, he inquired whether there were any serological connexion between the organism and the human serum and that of recovered or immunised monkeys. Diphtheroids were rare organisms, but had given an enormous amount of trouble through the fact that they were found in the cultures after prolonged incubation. It was important that no causal significance should be attributed to these organisms without strict proof. It was, however, true that some of the diphtheroids were capable of infecting guinea-pigs and might produce the lesions described. The suggestion of an ultramicroscopic virus developing on cultivation into an ordinary micro-organism was novel. To take one example, the pleuro-pneumonia organism of cattle could be cultivated in tissue and was capable of developing colonies in artificial media, but it did not grow bigger or become microscopically visible.

Dr. G. W. M. FINDLAY mentioned one virus disease which was capable of being associated with secondary bacteriological infection. This was the virus myxomatosus in rabbits. He asked whether cultures had been taken from normal monkeys to see whether any diphtheroid organisms could be grown from them, and whether any controls were made on the rabbit's heart and kidneys to see whether they were inoculative to diphtheroids. Some viruses, he said, could survive a considerable time at 37° C., particularly the agent of the Rous sarcoma, which sometimes survived for a week in partially aseptic cultures similar to those used by Prof. Kuczynski. If a serum immune against a virus were mixed with the virus and the mixture inoculated, no infection followed. He asked whether this had been tried with the yellow fever organism.

Dr. **Harold Scott** gave an account of a paper by a Portuguese research worker on this subject, who had isolated from two human cases no less than 27 different organisms which he had enumerated under various index numbers. In particular this worker had found that the serum of recovered cases agglutinated a particular organism to a titre of 1 in 60. The speaker asked whether any cultivation experiments had been done with the serum of recovered cases by Prof. Kuczynski, and whether he had tested the Costa Cruz reaction for reduction of complement, which seemed to be absolutely certain in yellow fever. The organism, he thought, might be analogous to proteus X. 9 in typhus, or pneumosintes in influenza. These organisms had to be regarded with extreme caution. It must be clearly established that the bacillus was neither a concomitant nor a contamination, and that it was ætiologically connected with the disease.

Dr. C. **Fletcher** said that Prof. Kuczynski had not mentioned whether any rhesus monkeys which had recovered from the infections produced by the bacillary strains had been tested for immunity with inoculations of the virus. The importance of this work seemed to go much further than yellow fever. If it was correct, Koch's postulates went by the board, and old-fashioned bacteriologists received a profound shock. The whole question should be investigated further forthwith.

Dr. C. C. **Okell** remarked that, when working with Mr. Hindle, he had cultured the liver from a great many monkeys. He had, it was true, sometimes grown as many organisms as Dr. Scott's Portuguese worker, but under ideal conditions he never isolated anything, and did not believe that a bacterium had anything to do with yellow fever. If Prof. Kuczynski's work on the susceptibility of the guinea-pig were confirmed it would mark an entirely new era in laboratory technique. He only knew that he had injected a cubic centimetre of a vaccine, 1/10,000 of a gramme of which had killed a rhesus, into 12 guinea-pigs; after the whole staff had become tired of watching them they had been killed and found in prodigious health. Diphtheroids were the most treacherous of organisms, and of all bacteria which could be connected with yellow fever they were the class to be treated with the greatest respect. He required further evidence of their ætiological importance.

Reply.

Prof. **Kuczynski** replied that his criterion of yellow fever was the typical picture familiar to all those who had studied it. Costa Cruz had never maintained that his reaction was at all regular in rhesus. Prof. Bergmann had found that certain human cases showed a loss of complement. There was no destruction of the liver in guinea-pigs, but typical infections had been caused in rhesus monkeys after the fifth passage of the virus through guinea-pigs. Most of the infections had been long. Eight per cent. of monkeys produced new cultures if a very pure strain of virus was used, but the organism was not at all like the diphtheroid described in this paper. He had found absolutely nothing else. Purity of cultures depended upon the scrupulous care of the animals and the purity of the virus used. His experiments had fulfilled both these conditions. Careful tests had all been made with the contents of non-inoculated tubes before an inoculated tube was used. Material was only put into tubes which had been carefully tested for cleanliness. If these precautions were neglected, there was no wonder if a multitude of different organisms appeared in the culture. In reply to the suggestion that diphtheroids were not pathogenic, he could only point to his results, which he offered to repeat in the laboratory of a critic. Experiments on the toxin were nearing completion. Typhus could not be cultivated on his medium with human ascitic fluid.

CHELSEA CLINICAL SOCIETY.

A meeting of this Society, on Jan. 21st, with Mr. L. A. **Harwood**, the President, in the chair, was devoted to a discussion on

SWEATING.

Dr. C. E. **Sundell**, in opening, pointed out that the text-books made a number of diverse statements about the content and nature of sweat, and he thought their lack of agreement was largely due to the fact that different workers made their observations on different types of person. For instance, one book said that sweat was alkaline, another that it was neutral, and a third that it was universally acid. He thought that if the sweat were regarded as "cutaneous urine" this would give an explanation of the various reports on its composition. The best and most recent work on the subject stated that sweat was always slightly acid in reaction, just as the normal urine of a healthy person was always slightly acid. The degree of acidity of the sweat varied in different parts of the body; on the forehead, for instance, it was less acid than on the feet. Naturally, it was on healthy persons that most of the physiological work on the subject had been done; when dealing with certain forms of disease striking differences were noted. For example, with an angry big toe and a temper to match, the skin over a gouty joint was dry and hot, but if it was moistened and its reaction was tested, it would be found to be intensely acid, whereas the fellow big toe, which was healthy, would only show faint acidity.

Acute Rheumatism and its Treatment.

Dr. Sundell's own work on the subject had been mainly on sweating as a curative measure in rheumatic affections. Rheumatism seemed to be associated with some alteration in the activity of the skin. Patients with acute rheumatism were well known to sweat profusely, and their sweat was very acid. There was, however, an important exception to this rule —namely, acute hyperpyrexia. In this condition the patient who probably reached a temperature of 108° or 109° F. before he died was the patient who did not sweat. Two years ago he had a good example of that in hospital. The patient had a definite acute attack of rheumatic fever, with a temperature of 108° F., and his skin was bone dry and it was covered with tiny miliary lesions looking like blisters. The contents of these were acid, and he supposed the fluid in them was sweat which had not reached the surface. This patient failed to react to the many measures taken with the view to making him perspire, and he died, Dr. Sundell thought, because he did not sweat. Very probably the child of rheumatic tendency had gross imbalance of the cutaneous secretions. Sometimes the skin was dry, sometimes there were night sweats. Night sweats did not always mean that the particular patient was tuberculous. Broadly, it could be said that the rheumatic case of the chronic or subacute type perspired but little, whereas the acute type did so profusely and copiously.

He wished to speak particularly of the treatment of cases of rheumatism, and to relate a method, not his own, which he had found very successful. Suppose that a youth, aged 16, came into hospital with inflamed joints and with a temperature of 102° or 103° F. Probably the physician said, "Let us give him salicylates, bring his temperature down, and cure him." That was the course Dr. Sundell had himself adopted until he "saw the light." His present practice in these cases was to refrain from giving salicylates and to keep the patient warm in bed and promote sweating as much as possible—i.e., leaving the fever without any active treatment. If the patient did not sweat as freely as was desired perspiration could be increased by means of baths. On this treatment he had found that these cases of acute rheumatism cleared up extraordinarily well, and for good; for after this treatment he had not had the relapses and disappointing recurrences which were all too frequent after the salicylic régime. This warm bed and sweating treatment was that which was mostly relied upon before, about 1870, salicylates were first applied as a medicine to disease; the patients were given some alkali, put to bed, and encouraged to sweat, opium being administered if the pain was very severe. Dr. Sundell did not agree with those who said these children were suffering from an exacerbation of a smouldering infection; he did not think the lingering rheumatism in children had any relation to microbes.

As to the eliminative effect of sweating in other conditions, the older physicians, and some now practising, regarded sweating as one of the best means of protection against mercurialism when mercury was used in the treatment of syphilis. Especially if the sweating measures were accompanied by the use of vapour baths, stomatitis and other mercurial manifestations could usually be kept well at bay. An important part of the subject under discussion was the cause of night sweats and the best means of treating them. He recently had under care a tragic case in which night sweats were a striking feature; there was drenching perspiration several times a night. It was a case of advanced carcinoma, leading on to generalised carcinomatosis, and during the last three months of life the sweating was one of the most distressing features. A very large number of means were tried to stop it, but without any success until a homœopathist came along and suggested arsenic. Forty-eight hours after this was given the sweating stopped; Dr. Sundell could not explain why. Moreover, it did not recur for three weeks, and was then amenable once more to arsenic. The case just related had a gynæcological origin, and he had heard it said that the sweats associated with the climacteric were confined to the head and trunk, the arms and legs not being involved. He would like to know whether that statement was true.

Functions of the Skin.

Dr. **Henry MacCormac** said that when he was being taught dermatology he was led to believe that the skin was a gas-tight and water-tight envelope in which there were a number of sweat and sebaceous glands, and that the function of the skin, apart from them, was a protective one, shielding the body from external agencies, chemical, physical, bacterial. Sweat was said to be subordinate to the functions of the kidneys and little notice was taken of it. Santorius, a contemporary of Harvey, devised an ingenious balance on which he lay for days measuring the intake of food and fluid and weighing his excrement, and much of his results, arrived at after 30 years, stood at the present day. That authority described "sensible perspiration" and "insensible perspiration." By the first he meant the appearance on the skin of droplets of sweat, a condition which developed when the external temperature rose to or beyond 33° C. Experiments had shown that at the time this occurred there was a considerably increased discharge of CO_2 in the blood—i.e., about four times more than before. A French worker applied dry paper to his skin, allowed it to remain in contact with the skin 30 minutes, then soaked the paper in silver nitrate and exposed it] to the sun. There then appeared on the paper a number of white spots or points, which were caused by the sodium chloride in the sweat, and he said those points corresponded with the orifices of the sweat ducts and that insensible perspiration was given off during that period. He went further and applied belladonna and atropine to the skin, and demonstrated that where these had been applied this phenomenon did not develop. There was a congenital ectodermal effect in which people had a total absence of sweat glands, and in such persons investigations had been carried out on the effects of heat. It had been shown that in their case both water and CO_2 could pass through the skin; thus one could conclude that the skin allowed water and CO_2 to pass through it independently of sweat glands. This had been more recently confirmed by Prof. J. S. Haldane in his work on miners and others who worked in high temperature conditions, and therefore sweated profusely and drank large quantities of fluid. In the form of sweat these men passed out large quantities of sodium chloride, so that they actually suffered from a deficiency in the body of that compound, and this deficiency gave rise to a train of symptoms, such as cramps, debility, and weakness. Haldane had shown that this insensible perspiration could occur apart from the mediation of sweat glands. Miners got over the tendency to cramps and debility by eating some form of salt diet, such as kippered herring or kippered bloater in the morning.

Dr. **MacCormac** thought it important not to consider the sweat glands alone as such, but to take into account also the sebaceous glands, which were equally important and which worked with the sweat glands; indeed, the sebaceous glands could take on the function of the sweat glands. The sebaceous glands poured out a secretion on the skin which acted as an important protective substance; and he had often wondered whether the modern habit of taking one or two hot baths a day, accompanied by the liberal use of soap, did not remove from the skin this substance and possibly pave the way for a number of dermatological conditions. Sabouraud mentioned the case of a mother of seven children who brought three of them for a skin condition, which was thought to be contagious. It was found that only these three were attended to by an English nurse, and the condition of their skin was attributed to the assiduity of her washings. It was interesting to reflect that ringworm of the scalp died out at puberty. So far as he knew there was no physical or chemical change in the hair of the head at that time, yet, when that time of life was reached, something made the hair an unsuitable medium for the growth of the ringworm fungus. He thought that pointed to something developing in the sebaceous glands to bring about this change. And there was probably a variation in the constitution of those glands in various parts of the body, because although a man was no longer able to develop ringworm on the hair of the scalp he could easily develop it on the beard, and very seldom did ringworm develop in the hair of the moustache. Possibly something similar obtained in sycosis. The sebaceous gland secretion could often be modified by small doses of X rays.

Discussion.

Dr. **R. A. Young**, referring to the treatment of acute rheumatism, said that before the introduction of salicylates the treatment of that disease was stated by a cynical Guy's physician to be "six weeks," and the speaker thought that was a more effective treatment than that now adopted. As to Dr. MacCormac's remark concerning sites of selection for ringworm, if members of medical societies would bring forward puzzling cases and facts, as well as their experiences, more real research would be done in this way than was often done in laboratories, valuable though the latter was. A man who made a brilliant diagnosis of a case did more real research than did the man whose life was spent amid test-tubes. In the early years of his Brompton Hospital experience night sweats were a great trouble, and they resisted the various drugs and other efforts. They were not now a real trouble, for these tuberculous patients who suffered in this way were placed on a rush bed near a window. Yet the most striking example of sweating which he had seen in recent years was in a case of pulmonary tuberculosis. For this patient artificial pneumothorax was tried, but had little effect. Sanocrysin did improve it, but after four doses the benefit passed off and the sweating was as severe as ever. Then his house physician put the woman into a modern hot-air apparatus, and she was able to turn on and off at will the electric bath. This did her good, and the sweating subsided a good deal. He had since seen another case of sweating very considerably relieved by this apparatus. That the skin supported and supplemented the secretion of the kidneys was an idea which was considerably supported by the facts, and it accounted for the benefit derived from hot-air baths in renal disease.

Dr. R. L. J. LLEWELLYN spoke of the great susceptibility of rheumatic subjects to changes in the weather, and argued therefrom the need for special care of the skin, particularly in inuring it to tolerance by alternations of heat and cold, always concluding with a cold douche, to tone up the skin. All patients were questioned about the action of their bowels; but their skin functions were seldom inquired into. Nature was always trying to restore the endocrine balance. Patients with acute rheumatism could be said to have the sweating diathesis.

Dr. F. J. MCCANN said that in the treatment of the sweating seen in women at the menopause he had found great benefit from ichthyol.

LIVERPOOL MEDICAL INSTITUTION.

AT a meeting of this institution on Jan. 9th a paper on

Low Blood Pressure

was read by Dr. E. NOBLE CHAMBERLAIN. After dealing with the physiological principles underlying the maintenance of normal blood pressure, he described the various ways in which the blood pressure can be reduced in disease, as by weakening of the myocardium and diminution of vasomotor tone. First, however, he called attention to the occurrence of low blood pressure in normal people. In a group of 60 medical students and doctors, of ages varying between 18 and 33, as many as 15 showed systolic pressures below 110 mm. They appeared to fall into two groups, one with good physique, athletic habits, and complete freedom from symptoms, and the other, who were subject to minor circulatory disturbances such as chilblains and cold hands, and were often of a neurasthenic disposition. The former group were in no way below par either physically or mentally, and were capable of both sudden and sustained efforts. In view of the hypotension in this group it was considered not proven that the circulatory disturbances in the second group were necessarily related to the hypotension. Shock and hæmorrhage, said Dr. Chamberlain, illustrated types of extreme hypotension which might be fatal if the systolic blood pressure fell below 60 mm. The low blood pressure in these cases was due largely to diminution of blood volume, resulting from increased vasomotor dilatation, and increased permeability of the capillary walls, which possibly occurred from the toxic effects of histamine-like bodies produced at the site of the trauma. Direct diminution of blood volume occurred in hæmorrhage. In acute infections, such as diphtheria, pneumonia, and typhoid, the blood pressure usually fell gradually during the illness, slowly rising again during convalescence. Sudden drops were usually of ill omen, indicating the presence of such complications as cardiac failure in pneumonia or hæmorrhage in typhoid fever. Sudden rises were also apt to occur in the acute delirium of pneumonia or the perforation of typhoid ulcers. The cause of the hypotension in these conditions was probably to be sought in the effect of bacterial toxins and of the products of bacterial activity in the tissues on the vasomotor system—a theory with some experimental substantiation. In chronic infections hypotension was very constantly present in tuberculosis, and was usually proportionate to the severity and activity of the disease. In a series of cases investigated by Dr. Chamberlain there did not appear to be any direct relationship between the temperature and the hypotension, though low blood pressure was nearly always present when the patient was much emaciated. The hypotension in these cases was partly due, as in acute infections, to the effect of bacterial toxins and the products of bacterial action on the tissues, but might, he suggested, be due to histamine-like substances formed in the process of caseation. In cardiovascular diseases it was to be noted that hypotension was comparatively rare, except as a terminal event. In 100 cases analysed by Dr. Chamberlain there was only one case of hypotension—a patient who died 12 hours later. These cases were divided into: mitral disease, 29; aortic disease, 42; myocardial disease, 29. Cases were only accepted as myocardial damage which showed gross electrocardiographic changes such as heart block and bundle-branch block. Dr. Chamberlain, however, called attention to the fact that in a number of cases of infective endocarditis examined by him the blood pressure was low in about half the patients and never above normal, although the majority of cases were lesions of the aortic valve where high systolic pressures were usual. He considered, therefore, that hypotension in valvular disease of the heart, unless accompanied by marked signs of cardiac failure, is suggestive of infective endocarditis, particularly if the course of the blood pressure is progressively downwards. Here, as in all cases, the value of knowing the individual's blood pressure variations in health was to be emphasised. That a fall in blood pressure would occur in infective endocarditis was to be expected, when one considered the frequency of hypotension in other infections. In endocrine disorders it had long been known that hypotension was a common feature of Addison's disease, but cases had been described recently where the blood pressure remained normal in spite of the advance over many years of all the other characteristic symptoms of the disease. This, and the experimental evidence that destruction of the suprarenal medulla in animals was often accompanied by no ill-effects and that the amounts of adrenalin in the blood of normal beings was not sufficient to produce vasoconstrictor effects, made untenable the theory that the low blood pressure of Addison's disease was due to deficiency of adrenalin owing to destruction of the suprarenal medulla. The cause of the hypotension remained unexplained. In cases of pituitary insufficiency, as in Fröhlich's syndrome, low blood pressure was also common, probably owing to lack of pituitrin which might exert a pressor effect in the normal animal.

In speaking of treatment Dr. Chamberlain followed the lines of his article in the series on Modern Technique in Treatment in THE LANCET (1929, i., 889).

MERSEYSIDE HOSPITALS.—Last year the ordinary income of the Liverpool Voluntary Hospitals was £286,464, and the expenditure £314,337, leaving a deficit of £27,873. The necessitous persons who were treated without any payment numbered 8000; their aggregate stay was 138,000 days. The four Liverpool Hospitals spent £6600 in dressings, and £7271 in drugs. There were 10,445 cases for X ray treatment, and 480 for radium treatment, and 17,544 operations were performed. Attendances for electrical massage treatment were 127,121 and for artificial sunlight 11,605. The annual cost of the maintenance in hospital of persons unable to contribute to the penny-in-the-pound fund is stated to be at least £70,000.

Reviews and Notices of Books.

PROBLEMS OF NEUROSES.

By ALFRED ADLER. With a Prefatory Essay by F. G. CROOKSHANK, M.D., F.R.C.P. Edited by PHILIPPE MAIRET. London: Kegan Paul, Trench, Trübner and Co., Ltd. 1929. Pp. 178 + xxxvii. 8s. 6d.

Dr. Crookshank opens with a lively criticism, in which most psychopathologists would concur, of what Biot has called the necrological and veterinary schools of orthodox medical thought. He then points to a great, though unofficial, therapeutic advance, instanced in the new methods by which the cardiac neuroses—sources of suffering and wastage greater than that due to the so-called "organic" heart diseases—have, after centuries of neglect since Harvey's time, become more amenable to treatment than are fibrillation, heart-block, and flutter. Believing that the most important contribution to the psychological school of medical thought will prove to be due to Alfred Adler, he gives a description of that physician's theory of organ inferiority, as applied to physical dysfunction and disease or the development of neurosis. Then follow an account of individual psychology and an eulogy of Adler "who, in easy, pleasant, simple sentences, helps us to solve the greatest and most important problem of all, that of understanding human nature." The case-histories related by Adler himself emphasise his view that the neurotic symptom is designed for an end; they show, too, how the psychotherapist, by convincing the patient of this end, induces him to renounce it and take up anew the task of life. Adler's ready insight into human motives is manifest, and we can picture him successfully leading the patient along the road to self-understanding. It is difficult, however, to find any relation between his methods or views and psycho-analysis, although Dr. Crookshank tells us that the Freudian methods of investigation are frankly accepted by the author. It is true that he offers his interpretations of patients' dreams, but there is no hint of the revival of emotional memories not already accessible to consciousness—which is, historically and practically, the foundation of psycho-analysis, the key to the comprehension of the theory of the unconscious. The influence of such memories in the production of symptoms is equally ignored by Adler. The neglect of this aspect leaves, as it were, a naked-eye pathology, easily understood because it remains on the level of consciousness already familiar to us and makes no demands upon new conceptions of mental processes, but unsatisfying to anyone whose work has forced him to use such conceptions. There is ample scope for the application of Adler's methods among the multitudes of neurotic patients, but his theory covers only a part of our knowledge of psychic mechanisms.

A MANUAL OF MIDWIFERY.

For Students and Practitioners. Fourth edition. By HENRY JELLETT, B.A., M.D., F.R.C.P.I., L.M., late King's Professor of Midwifery, Trinity College, Dublin; ex-Master of the Rotunda Hospital; and DAVID G. MADILL, B.A., M.B., B.Ch., B.A.O., L.M., Gynæcologist to Adelaide Hospital, Dublin; ex-Assistant Master of the Rotunda Hospital. London: Baillière, Tindall and Cox. 1929. Pp. 1281. 25s.

EXTENSIVE revision has been found necessary in the preparation of this fourth edition of the Manual of Midwifery, and the authors have not hesitated to make use of experts in special subjects, while numerous recent references are given. The book, in fact, is up to date and complete in the letter of obstetrics; it is therefore regrettable that its spirit remains that of the obstetrics of ten years ago. The preventive side of midwifery is not given the prominence which it now deserves, and the inclusion of chapters on the various aspects of midwifery treated from this point of view would greatly enhance the value of the work. It is, however, well arranged and clearly written; its chief appeal will be to the post-graduate student and to the teacher.

In the main, the teaching is that of the Rotunda, although the book is not merely an exposition of Rotunda methods without due reference to others. It has one fault, besides the neglect of the preventive side, which is common to most text-books on midwifery; the minor abnormalities found during pregnancy are not given sufficient prominence. In practice major diseases and abnormalities are rarely missed, and usually receive correct treatment by the practitioner; but the minor degrees of disproportion, doubtful cases of postmaturity, and signs suggestive of early toxæmia tend to embarrass the medical adviser, especially when the text-book of his choice has not warned him of the frequency with which he will have to deal with them.

It is almost impossible to combine in one work definite teaching in preparation for examinations, instruction for the practitioner, and a philosophic outlook which will embrace the preventive as well as the curative side of any branch of medicine. This work succeeds in providing the first two of these in good measure, and readers must be content to look elsewhere for the third.

HYGIENE AND PUBLIC HEALTH.

(*Parkes and Kenwood.*) Eighth edition. Revised by HENRY R. KENWOOD, M.B., D.P.H., Emeritus Professor of Hygiene and Public Health, University of London; M.O.H., Bedfordshire; and HAROLD KERR, O.B.E., M.A., M.D., D.P.H., Professor of Hygiene and Public Health, University of Durham; M.O.H., City and County of Newcastle-upon-Tyne. London: H. K. Lewis and Co., Ltd. 1929. Pp. 823. 21s.

THIS manual was originally written by Dr. Louis C. Parkes, with whom Prof. Kenwood entered into collaboration in later editions, and now Prof. Harold Kerr has joined with Prof. Kenwood in bringing it up to date. Many passages have been deleted and the space filled with new material, the editing having been so cleverly done as to provide connected teaching; thus "Parkes and Kenwood" retains its high place in the rank of text-books in public health.

A book of this kind will always show variations in quality depending on the personal interest of the authors in the different branches of public health. We find, for instance, that the chapter on air and ventilation is excellent, although the description on page 154 of the relation between ventilation and diphtheria is not very scientifically expressed. The chapter on warming and lighting is likewise very good, although here, too, one misleading statement is made at the very commencement, which gives the impression that the desideratum in a good heating system is warming of the air. It would appear desirable to avoid reference to such commodities as smokeless fuel by commercial names, since many of those sold under proprietary names are of equal merit. In the chapter on infection the discussion of susceptibility and immunity is hardly adequate. No attempt is made to estimate the significance of modern observations on the transmission of communicable diseases in relation to mass immunisation by unrecognised infections. In places throughout the book various means of attaining an object are described without discrimination as to their relative value. This criticism, for instance, applies to the descriptions of the treatment of swimming-bath water with "electrolytic fluid" or continuous filtration. In the same chapter considerable space is given to the description and illustration of the sterilisation of water by means of ultra-violet radiation; if, as we believe, this is a very costly method, it is desirable that students should be told so. It is not strictly accurate to say that glass is a complete absorber of ultra-violet rays. On page 210 a reference to carbonic oxide appears to be intended for carbon monoxide.

In noting a few points for criticism we do not want to imply that they are important. The book in its revised form will be justly valued by all advanced students of public health and it will be used for reference in public health departments throughout the kingdom.

English Public Health Administration. By B. G. BANNINGTON, Sanitary Inspector, County Borough of West Ham. London: P. S. King and Son, Ltd. 1929. Pp. 325. 12*s.* 6*d.*

THIS second edition of a very useful work appears at an appropriate time in view of the reform of local government which the Act of 1929 is intended to bring about. Mr. Bannington has brought his book into line with present day public health law and practice, though fully aware that consolidation of the law will soon make it out of date. The range of the service is well covered, although the more modern and specialised medical branches of the work, such as those concerned with the health of school-children, venereal diseases, and mental deficiency, receive rather scant notice. The significance of the expansion of these important services might have been utilised more freely to emphasise some of the points the author sets out to make. Apart from this, the book contains much valuable information, some of which will be new even to those who administer health departments and teach methods of administration to others. It should find a place in the library of every medical officer of health, and will convey to students of public health a vivid idea of the service for which they are preparing.

INFECTIOUS DISEASES AND OTHER FEVERS IN INDIA. A Manual for Students and Practitioners. By PURSHOTAMDAS T. PATEL, M.D. Lond., M.R.C.P. Lond., D.T.M. & H. Cantab., Medical Superintendent, City Isolation Hospital and Maratha Plague Hospital, Bombay. Calcutta: Butterworth and Co. 1929. Pp. 784.

THIS is a handbook on fevers for the use of students and practitioners in India. The impression conveyed by a perusal of the book is that the material is incompletely digested and hastily arranged. Misprints are frequent, especially when the writer deals with scientific nomenclature. The reader will find much to criticise in the distribution of space. For example, a discussion of yellow fever, a disease which has never occurred in India, is included, while only two pages are devoted to undulant fever.

JOURNALS.

BRITISH JOURNAL OF CHILDREN'S DISEASES. Vol. XXVI. October–December, 1929.—In a paper on Experimental Pyelitis and its Relationship to Urinary Infections in the Infant Dr. H. F. Helmholz, of the Mayo Clinic, records experiments on rabbits which seem to favour the ascending mode of infection. The frequency of infection of the bladder, as compared with infection of the upper portion of the urinary tract, together with the fact that the colon bacillus after intravenous injection does not persist in the bladder when the upper part of the urinary tract is sterile, seems to indicate that in the rabbit the infection is of the ascending type. Although results from experiments on animals cannot be directly applied to man, there is enough confirmatory evidence from what is known of pyelitis in infancy to warrant the assumption that infections with the colon bacillus take place in the same way. In conclusion, Helmholz emphasises the importance of making a bacteriological examination of every case of pyelitis before a cure is pronounced, and of referring to a urologist for a careful study of the urinary tract all the cases in which the condition does not clear up after an intensive course of treatment by methenamine.—Dr. Leslie Cole and Dr. C. H. Whittle contribute a paper on Congenital Obliteration of the Bile-ducts, with a description of two cases in infants aged 5 months and 8 weeks respectively, and an account of the post-mortem findings.—In a Note on Combined Congenital Ectodermal Defects Dr. F. Parkes Weber points out that during the last 50 years a great many congenital and often familial ectodermal defects have been studied, including congenital alopecia, congenital hypotrichosis, monilithrix, and hypoplasia pilorum moniliformis often associated with more or less keratosis pilaris, various forms of congenital aplasia or dystrophy of nails, congenital dental aplasia, congenital anhidrosis, congenital asteatosis, and familial epidermolysis bullosa. Various examples of the association of these defects are quoted from the literature, and an annotated bibliography is appended.—Dr. Walter R. Bett contributes an article entitled Some Pædiatric Eponyms: Pirquet's Reaction, which contains a translation of Pirquet's original description of the reaction published in 1907, and a sympathetic sketch of his career, illustrated by an excellent portrait with his autograph.—The abstracts from current literature are devoted to treatment.

INDIAN JOURNAL OF MEDICAL RESEARCH. Vol. XVII., No. 2, October, 1929.—This number comprises some 28 papers, of which it is possible to give only the shortest summaries. D. C. Wilson and V. E. Pilley, under the ægis of the Indian Research Fund Association, have studied osteomalacia in India.—R. N. Chopra and his collaborators continue their studies on Indian drugs, and contribute papers on the kut root (*Saussurea lappa*), the pharmacological action of pseudo-ephedrine from the Indian varieties of ephedra, and observations on certain medicinal plants used in indigenous medicine.—I. M. Puri describes the male, female, egg, and larva of *Anopheles annandalei*, var. *interruptus*, and *Anopheles sintoni*, a new tree-hole breeding species.—H. H. King, C. G. Pandit, K. P. Menon, and I. P. V. Seetharama have made a thorough house-to-house filariasis survey in Saidapet with a note of the source of filarial infection in mosquitoes, and have also worked out the development of the filaria of the lizard, *Corrispiculum guindiensis*, in *Culex fatigans*. Both these papers are of very great importance to those interested in filariasis.—R. McCarrison has made further studies on the production of lymphadenoid goitres in rats.—T. A. Hughes and his assistants contribute papers on the effect of bile-salts, serum calcium, and phosphorus in health and disease.—K. V. Krishnan has attempted to standardise the antigen used in the syphilis flocculation reaction.—S. R. Christophers has made a collection of the anopheline and culicine mosquitoes from Madeira and the Canary Islands and here describes them, and also writes on hæmolysis by acid and basic quinine salts.—M. B. Soparkar has found a case of bovine tuberculosis in man in India.—R. B. Lloyd and S. N. Paul have investigated the serum protein changes in malaria and typhoid fever, and suggest that they bear some relation to immunity.—L. A. P. Anderson, M. G. Coombes, and S. M. K. Mallick have studied the interesting dissociation of *Bacillus avisepticus*, M. L. Ahuja has observed the electrical behaviour of rough and smooth variants of *B. typhosus*, and H. E. Shortt, R. O. A. Smith, H. A. H. d'Silva, and C. S. Swaminath have demonstrated *Leishmania donovani* in the fæces of a case of kala-azar.

MELKSHAM COTTAGE HOSPITAL.—Lord Radnor, Lord-Lieutenant of Wiltshire, last week opened an extension of this hospital which increases the number of beds to 31. The additions comprise a women's ward with nine beds, and a children's ward adjoining with eight cots. The opening coincided with the diamond jubilee of the foundation of the hospital.

THE LANCET.

LONDON: SATURDAY, JANUARY 25, 1930.

NOMENCLATURE OF RENAL DISEASE.

Existing classifications of Bright's disease are confusing and unsatisfactory, and it is not necessary to refer to text-books in order to make this discovery, because every medical man and, for that matter, every medical student is aware of the fact. There is, in fact, no branch of medicine in which dispute as to classification has been more active and unanimity more unobtainable. Terms such as chronic interstitial nephritis, parenchymatous nephritis, tubal nephritis, arterio-sclerotic kidney, and so forth, are employed in medical literature, but with different significations by different writers, and accessory labels, such as large white kidney, contracted kidney, granular kidney, and so on, are offered as alternatives or synonyms until the reader's mind is clouded. The magnificent attempt of Bright to correlate his clinical discoveries with post-mortem observations yielded results which for a time increased the general knowledge concerning diseases of the kidney, but it has long become apparent that naked-eye morbid anatomy is insufficient as a guide to the pathological processes present. Modern histological research, particularly in Germany, under the auspices of Aschoff, Volhard and Fahr, and Müller has, in recent years, opened up new avenues of investigation, and for many months advanced students of medical science in this country, amongst whom we include physicians of great experience and laboratory workers of established reputation, have awaited the publication summarising the work on nephritis which has been carried out during a long period in the Institute of Pathology at the London Hospital by Prof. Turnbull and his assistants. This has now emerged in the form of a report by Dr. Dorothy S. Russell, a brief summary of which appears on p. 204.

Dr. Russell's proposed classification represents an advance beyond the generality of orthodox teaching, and it is certain that the majority of serious writers in this field, whether in Great Britain, France, the United States, or Germany, will agree that it is closely in harmony with the views which they have individually expressed during the past decade. In the first place, she recognises a purely ischæmic group of renal degenerations, entirely separate both in its pathological and its clinical manifestations from the inflammatory group proper. It is the group to which Gull and Sutton originally drew attention, and Dr. Russell's work confirms the views of those who have maintained that, conspicuous as are the changes seen in the kidneys of such patients in the post-mortem room, they rarely present themselves clinically as obvious cases of renal disease, since the renal function is seldom sufficiently affected for the production of uræmia and its preceding symptoms unless a true toxic nephritis is superimposed upon the condition. In an introductory chapter Dr. Russell points out that this group cannot properly be included in the term "nephritis" or "Bright's disease," and then immediately proceeds to do so. Nor is it easy to see how she could have done otherwise, particularly as the average clinician has for years unconsciously confused this group with the more chronic forms of true renal inflammation. Having dealt with this important group, Dr. Russell proceeds to place all the true inflammations under the heading of "toxic nephritis," subdividing this into mild nephritis ("nephritis mitis") and intense nephritis ("nephritis acris"). The first of these divisions is admittedly nothing more nor less than the group which, under the name of "nephrosis," has caused vigorous controversy in all countries during the last ten years. As far as can be ascertained from a perusal of the report, the pathological department of the London Hospital has now given wholehearted adhesion to the contentions of Epstein and of the modern German school. In view of the recent criticisms by H. Gainsborough[1] and H. A. Christian,[2] this is a very significant fact; but it leaves the student in some perplexity as to why the term nephrosis, which has had the merit of provoking thought, has been abandoned in favour of a Latin word of somewhat vague significance. In the group "nephritis acris" is included the welter of cases in which active inflammation of the kidney is seen in all its early and late manifestations. "Nephritis repens" is regarded by Dr. Russell as a sub-group of nephritis acris, although she admits unfamiliarity with any of the early stages of inflammation leading up to the terminal condition of advanced renal inflammation of sclerotic and degenerative character which distinguishes this group. The text hardly makes it sufficiently clear to the reader that this is, in her opinion, a sub-group rather than a main category.

It is not in any way to belittle the importance of this work if we suggest that the difficulties are stated and helpfully discussed rather than solved. In spite of the amount of skilful labour that has been devoted to the compilation of the report, it is clear that it contains much controversial and some hypothetical matter. While proper stress is laid on certain biochemical tests and the deductions to be drawn from them, little or no reference is made to the important advances in biochemistry dealing with the composition of the body fluids, which have recently thrown so much light on the significance of œdema in various types of Bright's disease. The omission is perhaps a wise one. But we cannot help fearing that in evolving a classification of nephritis in harmony with the opinions of the majority of advanced workers in all countries to-day, Dr. Russell has imperilled the utility of her admirable investigations by proposing three new descriptive terms. It is given to few to recast the currency of a common topic and, unless these terms receive wide and early adoption, the unfortunate student will be plunged still more deeply into the bog of confusing nomenclature. This does not impair the value of the report as a classical study of the histology of Bright's disease.

MENTALITY AND ANÆSTHESIA.

It happens not seldom in the practice of medicine that some of the more vague and ill-defined factors in a case may yet be those of the greatest importance. We reckon among the ill-defined factors in an ordinary surgical patient all those attributes which may be included under the term "mental make-up," and it is interesting to see how striking a part these attributes may play in determining the behaviour of the patient under anæsthetics; interesting, and yet, it seems, not enough attended to. In a contribution to the current number of the *British Journal of Anæsthesia* Dr. Dudley Buxton deals partly with this aspect of the practice of anæsthetics, and calls to mind how the rôle played by the mental state of the patient may affect response to the selected drug. But his excellent dissertation is more closely concerned with the connexion between physical qualities in the patient and the production of anæsthesia. Every practising anæsthetist is aware of the striking difference displayed by different patients in their reaction to anæsthetic drugs; he does not always realise, however, how largely that difference is an affair of the psychological, rather than the physical state of the subject. The teacher of anæsthetics is accustomed to point out to the students under his instruction the discrepancies between the way in which the typical heavy physical worker—the coal-heaver, for example—reacts to an inhaled anæsthetic, and the reaction displayed by an underfed shop assistant. Dr. Buxton points out, similarly, the contrast between the behaviour of the thick-necked, red-faced, muscular subject and the thin pale female when submitted to anæsthesia. But while he is careful to accentuate the many differences in behaviour under anæsthetics occasioned by differences in physique, he is, we think, not so anxious to bring to mind the very extraordinary differences in conduct which are entirely dependent on psychological differences in patients.

---

[1] Quart. Jour. Med., 1929, xxiii., 101.

[2] The Lancet, 1929, ii., 340.

Now, to our thinking, this source of difference in behaviour is often more important and more influential than any produced by the variations in physical attributes. It is, for one thing, doubly important because of its very lack of obviousness. All the precautions necessary are likely to be taken to counteract undesirable results that may arise when the causes of the possibility or probability of these results are plain. When there is no such clear indication, then the precautions may be neglected, and the unwished-for phenomena, when they arise, may be difficult to cope with. There are, for example, people who give no indication by their behaviour at the start of inhalation, or by their manner generally, that they will show any peculiarity with regard to the effect of anæsthetics. They are, also, apparently of ordinary physique. Yet very early in the course of the induction of anæsthesia they are seized—it may be suddenly seized by such violent mental excitement, resulting in extreme precipitate muscular action, that they may hurl themselves from the operating table before any attempt at control can be made. Fortunately, examples of this peculiarity in its severest form are unusual. But they are not too rare for every anæsthetist of experience to have encountered them once and again. The explanation of this unexpected, uncontrollable, and unconscious activity of the voluntary muscular system is in all probability to be found in impulses arising from the cells of the lower layers of the cerebral cortex, the presumed seat of the "unconscious mind." And the impulses arising from this site are due to impressions placed there by previously received stimuli, these stimuli having been received generally during consciousness. This hypothesis at any rate offers a simple explanation for the familiar fact that the kind of phenomena we are considering here were unusually common among men who had endured the horrors of prolonged trench warfare and the stress and emotion called forth on the battlefield; these being subsequently repressed in ordinary life had so stamped themselves on the brain that the moment conscious control was withdrawn they took command. The officer who had led his men over the top leaped from the dentist's chair to do the same again, and the private soldier, who had saved his own life by dealing another a death-thrust with the bayonet, hurled the attendant nurse away from the table by which she stood while he became unconscious. These violent exhibitions which occur after the patient has lost consciousness may be regarded as the outcome of a kind of dream, and the relationship is well recognised between dreams, the hallucinations of unstable minds, and the mental states which occur in association with anæsthetic drugs.

It is of the first practical importance that the mental aspects of anæsthesia should be fully recognised, and that every step should be taken to ensure that the experience leaves no unpleasant, certainly no terrifying, impression. This is of particular importance with children, for, wrongly managed, the administration of anæsthetics may plant in a child's mind a fear which throws a shadow over his whole life, and which will certainly render any subsequent entrance to anæsthesia, should one become necessary, dreadful to the patient if not really dangerous.

◆

MEDICINES IN THE MASS.

It is recorded that one, Samuel Jessop, who died at the age of 65, in the year 1817, had such an inordinate craving for physic that in 21 years he took no less than 226,934 pills, besides 40,000 bottles of mixture; and in 1814, when his appetite increased, his consumption of pills was 51,590. "Truly," says William Ward, in whose quaint memoirs we find this remarkable story, "he must have thought with the prophet, 'The Lord hath created medicines out of the earth, and he that is wise will not abhor them.'" In the absence of evidence to the contrary it may be assumed that the late Mr. Jessop holds the record as a pill swallower, but there were others who ran him pretty close as, for instance, David Hartley, who ate 200 lb. weight of soap, and a certain bishop who drank a butt of tar water. From all this it seems clear that the Englishman's fondness for medicines is no new thing, but rather is a tradition that has been handed down from father to son. And so, as Steele observed, there arise in one generation after another quacks and those that are their prey. More than 100 years ago England was called the "paradise of quacks," and the title still has its claim. In the nature of things there is, of course, a difference between the nostrum monger of to-day and his prototype of old, for this is an age of mass production, while the other was an age when output was limited to the capacity of a man's hand. But in spite of, or because of, mass education, the credulity of the public is unchanged and unchanging. There is probably as much money spent on teaching the people that quack medicines are good for them as on any other single purpose, and so long as the nostrum industry is allowed to say what it likes, and the newspaper industry is allowed to print what is said, quackery will continue to flourish.

It is a deplorable fact that public opinion is not against secret remedies; but so much money is being spent on educating the public to believe in them, that the public intelligence is perverted. We have made some progress, it is true, to arrest the evil. For instance, no Government in our time has engaged in the quack medicine business; this is a step forward, for in times past governments have paid large sums for the purchase of nostrums. Thus in 1739, the House of Commons voted £5000 to Joanna Stevens for a solvent to remove stone, notwithstanding which, said a writer 90 years later, "there have been as many human calculi, since formed by His Majesty's liege lithotomical subjects, as would macadamise one side of Lincoln's Inn Fields." Incidentally, it was DAVID HARTLEY, the soap fiend, who was instrumental in obtaining this grant for Mrs. STEVENS, and it is sad to reflect that he himself died of the stone. The Parliament of England went out of the quack medicine business many years ago, and the moral outlook has been improved to that extent; but it is humiliating to have to admit that beyond ceasing to encourage quackery no Government in this country has done anything to discourage our Jessops or to protect medicine-taking dupes from medicine-making pretenders. Let us make our position quite clear. We do not condemn proprietary medicines en bloc, while we deplore the license enjoyed by the vendors of worthless remedies. Here we feel it to be our duty to point to the need which exists for some restraint on the zeal of those engaged in the traffic. Just before the war there was a Bill before Parliament which aimed at the prevention of some of the abuses which are part and parcel of this unwholesome business, and there were good prospects of the measure passing into law, notwithstanding the several vested interests which it affected. The Bill was based upon the recommendations of a Royal Commission (published as a supplement to THE LANCET, Jan. 10th, 1925), and by its main provisions it sought to prevent the sale and advertisement of "cures" for incurable diseases, and to prohibit the making of unjust claims as to what a secret remedy could do. It attacked only the obviously fraudulent side of the industry, and left open for exploitation by drug makers, enthusiastic for their own preparations—an even wider field than is available for cultivation in any other civilised country. We would that the present Government, despite its obvious lack of time in which to meet its commitments, would take this Bill out of its pigeon-hole and at least give it an airing. No honest man would stand to lose anything if it became law, and no hypochondriac would be stinted unduly in the practice of his hobby. The secret remedy evil is rapidly increasing in this country because ours is the only nation which does nothing to check it. Profits are being made among us by aliens through methods which if employed in the land of their birth would render them liable to segregation as enemies to society. This is a preposterous state of affairs. Mass production, big newspaper circulations, and ever-widening of the channels of distribution are continuing to spread the evil to such an extent that it may soon become a national vested interest, and as such be almost impossible to destroy. Our staple industries are in a bad way, unemployment and shortage of money are acute; and yet the turnover of quack medicines is bigger than ever it was, and many people are spending on rubbish what they ought to be spending on food. Our administrators should look into this matter; the spade work has already been done, and, as we have said, the appropriate Minister will find waiting in his Department a considered measure which if passed into law would afford some protection for the ignorant and quell an abuse which humiliates this country in the eyes of the world.

We do not think that pharmacists as a class would oppose the desired legislation, notwithstanding that it is through their hands that proprietary articles and secret remedies are passed to the ultimate consumer. In a recent statement, which has been accorded wide publicity, the President of the Pharmaceutical Society advised chemists to set their faces against the sale of drugs through automatic machines. There are obvious reasons why such a method of distribution should be condemned, and one of the reasons stressed by the President was that the employment of automatic machines by chemists detracts from "the personal value of their services to the public." This is true enough, and it is none the less true that a pharmacist who sells to the public a ready-made packet of a compounded drug of whose ingredients he is kept in ignorance by the manufacturer is also doing something which detracts from the personal value of his services. In the one case it is the pharmacist who employs an automatic machine and in the other it is the proprietor of the advertised nostrum who employs the machine; in the one case the machine is made of wood or metal and in the other case the machine is an educated human being. What personal service does the pharmacist render to the public when he hands over to a purchaser a box of pills he knows nothing about? Quite obviously he is rendering a disservice if he knows that the pills cannot possibly do what the advertisements claim for them. We regard the pronouncement of Mr. MORETON-PARRY valuable both in the interest of pharmaceutical chemists and the public; carried to its logical conclusion this statement must have a wide influence on the distribution side of the secret remedy industry. The time may come, and we hope it is not far distant, when British pharmacists will come into line with their Dutch confrères. As was recorded in our last issue (p. 168), at the instigation of the chemists in Holland a commission has been framed for the purpose of controlling the advertisements of medicinal preparations. This is highly commendable on the part of the Dutch chemists, and we hope that the President of the Pharmaceutical Society will carry his campaign against the automatic distribution of drugs a step further by advising action by the members of the Society, over which he presides so judiciously, on the lines of the Dutch programme.

Annotations.

"Ne quid nimis."

VITAL STATISTICS FOR 1929.

THE Registrar-General has issued a provisional statement of the figures for birth-rate, death-rate, and infantile mortality during the year 1929.

—	Birth-rate.	Death-rate.	Infant mortality-rate.
England and Wales ..	16·3	13·4	74
107 county boroughs and great towns, including London ..	16·7	13·8	79
157 smaller towns ..	16·0	12·3	69
London	15·9	13·9	70

The smaller towns are those with a population in 1921 of 20,000–50,000. The death-rate for England and Wales (which is based on the estimated population for 1929) relates to the whole population, but that for London and the two groups of towns (based on the 1928 estimate) to the civil population only. Birth-rate and death-rate are per 1000 population. Infant mortality-rate per 1000 live births.

The Registrar-General remarks that the birth-rate is 0·4 per 1000 below that of 1928 and is the lowest recorded. The death-rate is 1·7 per 1000 above that of 1928, a rise practically confined to the first quarter of the year, and due to the epidemic of influenza in the spring and the severe weather in that period. The infant mortality-rate has increased from 65 to 74 per 1000 live births, a rise probably due to the same causes. These provisional figures, which are not likely to require substantial modification, have been issued for the information of medical officers of health.

AN AUSTRIAN THAUMATURGIST.

Our Vienna correspondent tells us of the widespread fame as a wonder-healer achieved by a man named Valentin Zeileis in the small village of Gallspach in Upper Austria. Zeileis, who is now 56 years old, is a former peasant who has been experimenting with electricity from his boyhood, and has for 20 years past had wide vogue among his brother peasants. Now hundreds, even thousands, of patients are flocking daily to his office, where they have to disrobe *coram publico* and are seen by the "doctor" (as he is called) simultaneously in groups of 10 to 15. The great man uses a "diagnostic rod," being a glass tube containing radium emanation through which is passed a powerful high-frequency current. This rod or wand is moved over the body of the patient until it becomes fluorescent over any diseased or abnormal part. There is no doubt about the fluorescence, for the patient can see it, but its provenance is obscure to everyone but Zeileis himself. The treatment is then ordered. This consists chiefly of electro-static, high-frequency current, or hard X rays applied several times within a minute or two, or some combination of these with radium. The course of treatment lasts for 10 days or a fortnight, sometimes longer, when, our correspondent is assured, many patients who have already suffered at the hands of their own medical men return home relieved of their troubles. The place is in fact a veritable Lourdes, which it resembles in the nature of the diseases cured, which are mainly of a neurotic type with a sprinkling of rheumatic and pseudo-paralytic affections. Naturally all sorts of other sufferers, medical and surgical, come to seek Zeileis's advice, and he is shrewd enough to recognise where suggestive treatment will be useless or harmful, sending some away and sending others to medical men who believe in him, or at least affect to do so. Ethically the situation is interesting, for Zeileis's eldest son, who is working with him, has obtained the degree of M.D. in Austria, which, our correspondent says, makes it impossible to charge the father with quackery, as has been done on several previous occasions. When these cases came before the Court, numbers of staunch believers, of cured patients, and even of medical men, supported Zeileis's claims, with the result that he has remained unmolested since. He charges no fee for his services, but is always offered a trifle. Lately, in response to vehement attacks from the medical side, he has publicly disclosed the nature and technique of his electrical treatment, as briefly outlined here, and no doubt his experiments will be repeated in other quarters. It seems to be admitted that he and his assistants have had good results in some grave cases. In the last stage of this remarkable story Zeileis and his son have built an enormous institute in Gallspach, fitted up on the most up-to-date lines, in which 6000 patients can be treated a day. Here not only electrical but also other kinds of physical and hydrological treatment are given. Our correspondent remarks, in conclusion, that the flocking of ill persons to such centres is an indication that current medical knowledge does not (in Austria) completely satisfy the needs of suffering mankind.

REMEDIES FOR SEA-SICKNESS.

For sea-sickness Dr. Karl Muley,[1] of Istambol (Constantinople), gives good reports of a preparation called "otreon" (Höchst), recommended as an antacid. The tablets contain carbonates of bismuth and of magnesia, with 1 per cent. of papaverine and a foam-producing element, and Dr. Muley has found that they relieve nausea ashore. Thinking that the discomfort of sea-sickness is due to the dragging of viscera on the nerves of the diaphragm or peritoneum it seemed to him likely that papaverine would dull the afferent impulses from that region and so allay the vomiting, while the foam produced would distend the stomach and ensure that the papaverine made contact with the whole surface of the mucous membrane. The tablets, two of them, are to be taken with or without water, and swallowed whole. Relief has come in most of his nine cases within half an hour. It may be noted in passing that one of the literary magazines for November of last year recommends two forms of treatment for sea-sickness—one of them ginger-beer and the other antacid drugs. Their virtues are perhaps combined in this of Dr. Muley's. Possibly gas in the stomach may help to prevent the viscera from moving separately. Tight belts are often worn with this object.

Atropine as a vago-depressor has been in vogue for sea-sickness since 1913, and has proved of undoubted value. J. Bohec,[2] surgeon on the trans-Atlantic liner *Ile-de-France*, states that until last year he used atropine sulphate, but found it to have certain disadvantages. Its action is brief owing to rapid elimination, and the danger of poisoning makes it an unsuitable remedy for self-administration. In some cases the depressor action on the vagus is associated with a stimulation of the medulla, and hence of the vomiting centre; this type of case has been found to respond to atropine and morphia administered together. In 1927 Fischer suggested the use of lævo-rotary hyoscyamine, with scopolamine and mandragora; with these drugs the vago-inhibition of the hyoscyamine is augmented by the scopolamine, while the stimulation of the medulla due to the hyoscyamine is opposed by the depressor action of scopolamine on this centre. Bohec, working on the same principle, now employs a preparation of all the alkaloids of belladonna in the pure state, called "bellafoline;" this contains hyoscyamine, scopolamine, choline, asparagine, chrysatropic acid, and other alkaloids. The action is twice as marked and twice as long in duration as that of atropine, hence the dosage is smaller and safer; the toxicity is equal to that of atropine. Bellafoline can also be used in combination with a narcotic having a central action such as gardenal, and Bohec has made use of a preparation of this kind known as "belladenal." Bellafoline is taken before embarkation and during the early days of the voyage, and subsequently a tablet can be taken when the traveller feels an attack to be imminent. In the case of acute sea-sickness without employment of previous preventive measures it is stated that bellafoline has been given hypodermically with good results.

THE CHICAGO WORK ON INFLUENZA.

Prof. Falk and his colleagues have now made a preliminary report[3] on their work on influenza. The investigation consisted in the bacteriological examination of the blood and upper air-passages of patients and the experimental infection of monkeys, with subsequent cultural examination of these animals and further serological work. During the height of an epidemic in Chicago 1928–29 16 rhesus and capuchin monkeys were sprayed with material from eight human cases of influenza or from monkeys infected from them. Many cultures were made and examined from human patients. Twenty-eight monkeys were given a disease "closely resembling influenza" by spraying the nose and throat with 12 cultures of the presumed causal organism obtained from the blood of patients or by exposing them to contact with infected animals. The proportion of successful results with the two methods is not stated. Mild clinical influenza was produced in three rhesus monkeys caged with one which had been infected by spraying. Some evidence of antibodies to the cultures used was also "very commonly" obtained in the blood of 50 persons shortly after the epidemic. The cultures to which most ætiological importance was attached consisted of an organism belonging to a group of streptococci which was isolated 48 times from man or experimentally infected monkeys. These organisms which the authors call Group I. were characterised as highly pleomorphic, green-producing streptococci, which vary in their Gram-staining and fermentative properties, are not bile-soluble and are facultative anaerobes. These were not found normally in the blood or respiratory tract of monkeys. The streptococcus they consider similar to or identical with an organism described in an investigation of influenza in 1918–19 and more recent outbreaks. Other cultures, especially a group called Ia, appeared to have some relation to infections in man and animals, but were not so definitely associated with influenza.

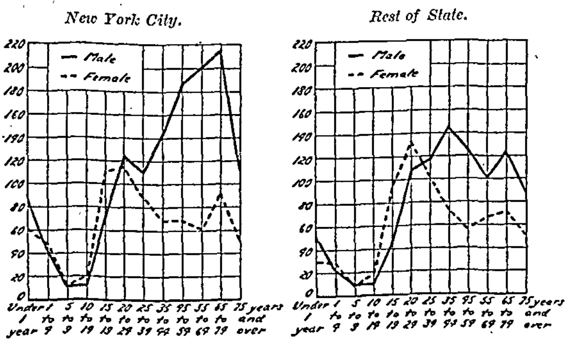
[3] Falk, I. S., Harrison, R. W., McKinney, R. A., and Stuppy, G. W.: Jour. Amer. Med. Assoc., Dec. 28th, 1929, p. 2030.

Making all allowances for the great bacteriological difficulties presented by the streptococcus group it does not seem certain from the evidence available that a definite streptococcus had a common primary ætiological relation to the cases of human influenza. There remain a number of points which need clearing up before it can be said that an epidemic of influenza was due to a well-defined species of streptococcus. The possibility that the initial infection was due to a virus does not appear to have been excluded, though such an infection is widely held to be the essential cause of influenza. That complications and pathological changes occurring in influenza epidemics are often due to infections with streptococci which invade a large number of closely associated cases is generally accepted, though attempts to establish this view have not often been so vigorously carried out and supported by experiments on monkeys. As was indicated in our annotation of Dec. 21st, 1929 (p. 1321), there are many difficulties in the way of accepting the work of Prof. Falk and his colleagues as having solved the whole problem of the ætiology of influenza. It is only fair, however, to add that such wide claims as were made in the lay press do not appear in the preliminary report. A full account of the investigation is promised shortly.

VITAL STATISTICS OF NEW YORK CITY.

THE records of life and death of the State of New York have become among the most important in the world, and the 49th annual report of the State Department of Health, dealing with experience in the year 1928, is an important volume, not only for the State itself, but as enabling comparisons with countries in the Old World to be made. We say, advisedly, comparisons with other countries, for the sovereign State of New York has a population of over 11½ millions. It is by far the most populous of the States of the Union. Of this population six millions live in the city of New York, the remainder in the many large towns and counties of the rest of the State. Both Dr. Matthias Nicoll, the State Commissioner of Health, and Dr. J. V. De Porte, the director of the division of Vital Statistics, can be congratulated on the increasing value of this report, and on the efforts being made to secure complete accuracy. In the past it has been difficult to be sure that comparisons between different towns and between rural and urban districts of the State were trustworthy, owing to the absence of a complete relegation of all deaths in outside institutions to the administrative districts in which the deceased had resided. Now tables are given enabling one to correct records by resident rates from all causes, for tuberculosis, cancer, and automobile accidents. A distinctive method is adopted for automobile accidents, which are corrected for place of occurrence of the accident. The allocation secured in these instances gets rid of a serious source of fallacy, while the second even more important source of fallacy, that of differing age-distribution of population, can be checked by the death-rates given in the report for separate age-groups. The importance of the correction is well seen in the statistics of tuberculosis. By allocation of deaths according to residence, the tuberculosis death-rate of New York City is increased by 11 per cent., and that of the rest of the State is reduced by 13 per cent. Similar allocation changes the fictitiously high death-rate of rural districts, which, instead of being 26 per cent. higher, become 35 per cent. lower than the urban rate.



Death-rates per 100,000 from tuberculosis (all forms) in 1928.

The difficulties must be very great, but we hope that it may soon become practicable to give for all the areas within the State a complete allocation of death, which will make the report even more valuable than at present, as a means of comparison, and as a stimulus to investigation and reform in the areas with less favourable statistics. Against diphtheria the State organisation has done remarkable work in the immunisation of young children. These efforts have been eminently successful in reducing diphtheria in the districts in which the campaign has secured widespread immunisation; but so far as the experience of the State as a whole is concerned, it may be noted that in 1928 the death-rate from diphtheria was 107 in New York City, and 39 in the rest of the State, as compared with 81 in England and Wales. The comparison thus made is, however, unfair to New York State, unless we bear in mind that over a series of years diphtheria is several times heavier as a cause of death in continental than it is in insular countries. Probably, therefore, the results just quoted imply that New York State is already reaping some of the good results attainable from its admirable work for immunisation of children.

One further point may be extracted from the report out of the many which deserve study. It illustrates a point already under investigation both in this country and in the States—namely, the excess of death-rate from tuberculosis in girls over boys at ages 1–4, 5–9, 10–14, and 15–19. At all other ages, after the age of 20 has been reached, the tuberculosis death-rate in both countries is markedly higher in males than in females. The accompanying graphs taken from p. 40 of the report, show the differences between the two sexes at each age-period separately for New York and for the rest of the State. It will be noted that the excess of female tuberculosis begins at the pre-school age and continues right up to the age of 20. It is not explicable, therefore, solely by the greater amount of industrial and office work of girls in recent years. This, indeed, would scarcely explain it, as lads are subjected to similar conditions. The greater amount of outdoor life of boys may partially explain the difference; but the period of such temporary service. Permanent commissions will normally be offered to temporary officers on or before the completion of 12 months of temporary service. Temporary officers who do not then accept a permanent commission will not be eligible, save in exceptional circumstances, for the grant of a permanent commission at a later date. An officer appointed to a permanent commission whilst serving as a temporary officer under the above conditions will not receive the bonus of £100 for each completed year of service, but he will be allowed to count such temporary service for increase of pay, promotion, and retirement. All particulars may be obtained by application to the Under Secretary of State, the War Office (A.M.D.1), Whitehall, London, S.W.1.

PASSIVE IMMUNITY IN CHICKEN-POX AND MEASLES.

In the case of measles passive immunisation by means of convalescent serum has passed from the experimental to the practical stage, as witness the scheme of prophylaxis lately recommended to boroughs by the Council of the Metropolitan Branch of the Society of Medical Officers of Health. It was inevitable that, sooner or later, the same procedure should be applied to other diseases of unknown ætiology, such as chicken-pox and mumps. The use of convalescent serum to secure a temporary protection against chicken-pox is said to have been tried first in 1923 by Blackfan, Peterson and Conroy,[1] and since then it has been studied in various quarters. The reasons for immunisation are not so urgent in chicken-pox as in measles, since it is not destructive to life and well-being. But, as J. E. Gordon and F. M. Meader,[2] point out, cross-infection with this disease is always upsetting the harmony of hospital management, because it requires three weeks' quarantine, and there is the " additional disagreeable criticism which follows contraction of a secondary infectious disease, even in the absence of culpability on the part of hospital personnel."

These writers submit some interesting evidence on the incubation period and the period of infectivity of chicken-pox. In 54 out of 67 cases in which the incubation period could be calculated with precision the eruption came out on the thirteenth to the seventeenth day, the commonest being the fifteenth, and in no instance did it appear on the generally accepted maximum of the twenty-first day. Two cases in their experience throw light on the infectivity of chicken-pox before the efflorescence of the eruption, and while one indicated that chicken-pox is not infectious 24 hours before the appearance of the rash, it appears from the other that the patient was infectious at least nine hours before vesicles were noted. Gordon and Meader consider that these features of chicken-pox have an important bearing on serum prophylaxis, because the long incubation period gives the antibodies a chance to catch up the slowly multiplying virus, while the parallelism between the first unmistakable sign of the disease and its infectivity make it possible to determine with some certainty the time of possible infection of susceptible contacts. Owing to the high infectivity of the prodromal stage of measles—a stage sometimes prolonged to five or six days—contacts may be infected some time before the infecting case is definitely recognised, and the benefit they will gain from convalescent serum is correspondingly reduced; since to produce complete protection against measles the serum should be given in the first five days of the incubation period. We doubt if this aspect of measles prevention work has been sufficiently recognised. Almost all the preliminary work has been done in hospitals where the early signs of the catarrhal stage are likely to be noted promptly, and now that the method is to be applied in the field of general practice, we must not be disappointed if the percentage of completely protected children is somewhat less high. Whatever importance is attributable to the factors mentioned, the success which Gordon and Meader report from using convalescent serum in prophylaxis against chicken-pox is encouraging, a protection rate of 91 per cent. being claimed among susceptibles. They got their best results by giving an intramuscular injection of 10 c.cm. of a pooled serum obtained from convalescent patients one to two months after the eruption. Serum obtained two to four months after the eruption was less reliable, whilst the protective value of serum withdrawn five to ten months after the onset was poor. To forestall the criticism that absence of infection is not always due to prophylactic measures, they have been careful to include in their observations 81 cases in which exposure took place but no serum was used. Fifty-five of these exposed susceptibles took chicken-pox, and it is on the basis of this proportion of infections that they have calculated their protection rates in the serum-injected patients. The serum being homologous, no objection can be raised on the ground of serum sickness or sensitisation of the patient. As with other forms of passive immunity, the duration of protection is relatively brief; apparently it does not last much beyond the longest incubation period, since of 12 injected patients re-exposed to secondary cases two contracted chicken-pox.

We are aware of several experiments in passive immunisation against chicken-pox having been carried out in this country, and it might be worth while to take these further. The current remedies for limiting ward outbreaks are the prompt isolation of cases and the quarantine of susceptibles, preferably in small groups. In view of the limited isolation accommodation in many of our fever and children's hospitals, the dispersal of a mass of contacts is often only a counsel of perfection, and whole wards have to be retained in quarantine for three or six weeks or even longer. In this way it is a recurrent experience to find as many as 10 per cent. of the available beds of a hospital in which the normal ebb and flow of admission and discharge is seriously interrupted. This can hardly be regarded as satisfactory, and it may well be that immunisation provides the best remedy.

MINOR LENTICULAR OPACITIES.

In Vol. XX. of the Westminster Hospital Reports Mr. A. F. MacCallan remarks that the slighter forms of cataract are much more common than is usually supposed and may be present even in persons with full visual acuity. It is, however, questionable whether in the interests of the peace of mind of our patients these slight forms of cataract, at any rate such as are non-progressive, ought ever to be termed cataract at all. The phrase " opacities of the lens " would be preferable. Mr. MacCallan describes several varieties of the condition, nearly all of which are in the lens cortex and therefore cannot have been present at birth, apart from certain rare forms of lamellar cataract developing earlier than usual in the layers now known as the " fœtal nucleus." All these forms of opacity, including the one just mentioned, presumably owe their origin to some variety of defective nutrition affecting the lens fibres which are being continually developed from fœtal life to old age. In the case of lamellar cataract we know that the defect in nutrition is one that is often associated with rickets and defective enamel of the incisor teeth. In the case of the cortical opacities of all degrees found in adult life. In Mr. MacCallan's opinion the cause in the majority of cases is a condition of chronic focal sepsis. The nutrition of the lens is derived by osmosis from the aqueous humour whose composition is dependent on that of the blood. There is experimental proof that certain poisons introduced into the blood can cause cataract. In rabbits artificial cataract has been produced by feeding them on naphthalene. Mr. MacCallan's experience in Egypt proved to him that the poison of ankylostomiasis is capable of causing cataract. Diabetic cataract must be caused in a similar way. His belief is that in almost all cases of cataract, and also of those slight lens opacities which may be compatible with good vision, some focus of toxic absorption either has existed or does exist, and that it is our duty to seek for it in the teeth, nasal sinuses, or mucous membrane, tonsils, intestinal tract, or elsewhere. In a series of his own cases, while not all those with focal sepsis exhibited lenticular opacity, every one where this was present was found to have a condition of focal sepsis. Since, in another passage, Mr. MacCallan tells us that in two series of his own cases as many as 45 per cent. were shown, either with or without the slit-lamp, to exhibit some opacity of the lens, his figures may be thought to prove too much for his argument to have much weight, for the connexion of two such very common conditions as focal infection, past or present, and slight lenticular opacities is by no means necessarily one of cause and effect. (The percentage of 45 given by the author seems higher than his figures justify.) The particular condition of sepsis that is by far the most common is dental sepsis, and since it is rare to find anyone in middle life who has not at some period suffered from dental sepsis it is difficult to see how percentages in this connexion can prove anything at all. At the same time it must be admitted that there is considerable ground, prima facie, for attributing many forms of cataract to sepsis, a view for which Mr. MacCallan does not claim any originality. The presence of opaque striæ in the lens is due, as a rule, to the coagulation of the protein substance of which its fibres are composed, but incipient cases may be due to the presence either within or between the fibres of a fluid of different refrangibility which has not actually coagulated. From the latter condition recovery may be possible. In the former the opacities are permanent, but they need not necessarily be progressive. In any case, therefore, it is well worth while to seek for any existing focus of septic infection, whether in the teeth or elsewhere.

JAMES MACKENZIE INSTITUTE FOR CLINICAL RESEARCH.

IT *is now ten years since the late Sir James* Mackenzie founded at St. Andrews an institute with the main purpose of investigating the earliest symptoms of disease and the mechanism of their production. During its tenth year 150 new cases and 110 additional notes were added to the files, and 1271 specimens were examined in the laboratories. All the records have been reviewed and rendered as complete as possible, and the studies on the cytology of the blood were continued, as well as those on the ætiology of the common cold; the relation of respiratory catarrhs in young children to environmental conditions; the relation of the state of the tonsils to disease; and the variations in the temperature and pulse which are consistent with health, as distinguished from those which betray early signs of disease. New lines of investigation opened up during the year include an enquiry into the early manifestations of cancer, and a study of after-histories of patients with gastro-intestinal disorders, in an attempt to assess the prognostic value of radiological examination. The Public Health Department has succeeded in coördinating the work of the private and panel practitioner with that of the maternity and child welfare and school medical officers, and regards this administrative advance as one of first-class importance. Over 80 per cent. of all the children born in the burgh are supervised by the child welfare centre, the records of which include antenatal histories provided by the practitioners. The children are examined at regular intervals, however healthy they appear to be, and are observed continuously throughout their school years. In these ways the Institute is keeping alive the spirit of the great general practitioner and public health worker whose name it bears.

Sir Cuthbert Wallace has been appointed Director of Medical Services and Research to the Mount Vernon Hospital, Northwood, where the investigation of radium in the treatment of malignant disease is being actively pursued.

THE death occurred unexpectedly on Jan. 21st of Dr. Philip Boobbyer, who retired a year ago from the post of Medical Officer of Health of the City of Nottingham.

The Services.

ROYAL NAVAL MEDICAL SERVICE.

Surg. Lt.-Comdr H. Hurst to be Surg. Comdr.

ROYAL NAVAL VOLUNTEER RESERVE.

Proby. Lt. A. D. Bruford to be Lt.

Proby. Surg. Sub-Lts. to be Surg. Sub-Lts.: J. N. Matthews and W. J. Poole.

Proby. Surg. Lt. T. G. Evans to be Surg. Lt.

Proby. Surg. Sub-Lt. B. Blewitt to be Surg. Sub-Lt.

ROYAL ARMY MEDICAL CORPS.

The undermentioned Lts. (on prob.) from the secd. list are restd. to the estabt.: W. G. Harvey, D. A'Brook, and T. G. D. Coneys.

Lt. (on prob.) W. G. Harvey is confirmed in his rank.

Lt. F. H. A. L. Davidson relinquishes his temp. commn.

TERRITORIAL ARMY.

Second Lt. H. W. Davies, from 16th Lond. R., to be Lt.

INDIAN MEDICAL SERVICE.

The undermentioned officers retire: Col. J. N. Walker, Lt.-Col. H. A. Williams, and Maj. M. Prasad.

COLONIAL MEDICAL SERVICE.

The following appointments have been made: Miss J. G. E. F. Cummins, Medical Officer, Gold Coast; Mr. P. J. Cowin and Mr. E. O. W. Maxwell, Medical Officers, Kenya; Mr. W. McCoach, Pathologist, Nigeria; Mr. W. E. Thompson, Specialist Surgeon, Palestine; and Miss M. M. McDowall, Medical Officer, Sierra Leone.

INDEX TO "THE LANCET," VOL. II., 1929.

THE Index and Title-page to Vol. II., 1920, which was completed with the issue of Dec. 28th, is now in preparation. A copy will be sent gratis to subscribers on receipt of a postcard addressed to the Manager of THE LANCET, 7, Adam-street, Adelphi, W.C. 2. Subscribers who have not already indicated their desire to receive Indexes regularly as published should do so now.

POST-GRADUATE LECTURES ON CANCER.—The second lecture arranged by the Clinical Medical Studies Committee of the University of Sheffield in conjunction with the Yorkshire Council of the British Empire Cancer Campaign will be given in the Physics Lecture Room of the University on Tuesday, Feb. 4th, at 8.45 P.M., by Sir Lenthal Cheatle, Surgeon and Lecturer in Surgery, at King's College Hospital, London. His subject will be the Treatment of Mammary Carcinoma by Radiation, and all qualified medical practitioners are invited. Dr. J. Murdoch, Chief of the Department of Radium and Radiotherapy at the Brugmann Hospital, Brussels, has promised to give the third lecture of this series at some date in May.

Special Articles.

A CLASSIFICATION OF BRIGHT'S DISEASE.

In a report[1] issued by the Medical Research Council Dr. Dorothy S. Russell gives a detailed account of the minute structure of the normal kidney and of the changes in its structural elements that accompany the various pathological states described. Dr. Russell has availed herself of the data accumulated by Prof. Turnbull in the Institute of Pathology at the London Hospital, and of the clinical opportunities in the wards. Her attempt has been to supply working principles to enable the practitioner to pass from ascertained facts to an interpretation of the underlying structural changes.

Under the term Bright's disease have been included two kinds of disturbance of renal structure which can, according to Dr. Russell, be differentiated with certainty by the microscope, and which are due to two distinct pathological processes. One of these is a slow infarction due to arterial degeneration: an ischæmic nephritis. The other is an inflammatory reaction to bacterial or other toxins: a toxic nephritis.

Ischæmic Nephritis.

This may occur independently of toxic nephritis, and has then been called primary ischæmic nephritis. A certain amount is found in the kidneys of most adults; unusual degrees at any age are due to exceptional arterial degeneration and are in consequence most commonly complications of cardiovascular disease. The gross appearances of the kidneys show variations depending upon the nature of the arteries which are partly occluded. Severe degrees of primary ischæmic nephritis appear to give rise to occasional slight albuminuria and to the passage of hyaline casts into the urine, but no evidence has been obtained of any other interference with renal function. Any alterations in renal efficiency have been fully explained by heart failure, which so frequently complicates cardiovascular hypertrophy.

Inasmuch as there is no evidence that the actual condition of the kidney ever gives rise to any illness, it is doubtful whether primary ischæmic nephritis should be included in Bright's disease. Primary ischæmic nephritis may be complicated by a secondary toxic nephritis, but it does not render the kidney liable to this complication. On the other hand, primary toxic nephritis, at any rate of the kind distinguished as acris, tends to be complicated in its later stages by cardiovascular hypertrophy, and consequent arterial degeneration and ischæmic nephritis. Such secondary ischæmic nephritis is very seldom absent from the chronic examples of toxic nephritis, and in the most chronic form of toxic nephritis disturbances of the cardiovascular system may dominate the symptoms.

Histologically such secondary ischæmic nephritis can be distinguished with certainty from the associated toxic changes.

Toxic Nephritis.

This can be divided histologically and clinically into two main kinds. In one kind parenchymatous degeneration is the chief renal change and the inflammatory reaction is of low grade. Lipoid is typically very abundant. This kind of nephritis corresponds to the nephrosis of Volhard and Fahr, and the lipoid nephrosis of Munk; it has been distinguished histologically here as nephritis mitis.

Nephritis Mitis.—Examples of this have been found in an early stage before granulation and in an intermediate stage of granulation, but not in a late or chronic stage of sclerosis. In only one example of nephritis mitis in the intermediate stage was cardiovascular hypertrophy found, and the degree of hypertrophy was slight. Clinically nephritis mitis causes grave œdema, but no appreciable disturbance of renal function as estimated by the excretion of urea and dye: it gives rise to a hydropigenous nephritis. The mildness of the exudative inflammation is reflected in the cytology of the urine. Clinically the disease has no acute stage, and no appreciable difference was detected between the clinical symptoms in the early and intermediate stages. Death in all cases was due to an intercurrent infection, usually with pneumococci. Histologically nephritis mitis resembles the forms of nephritis that are symptomatic of endogenous toxins. No clinical evidence was obtained of the cause.

Nephritis Acris.—The other kind of toxic nephritis is distinguished histologically by the higher grade of inflammatory reaction, and has been called nephritis acris. The clinical characteristic of this nephritis is interference with renal efficiency: it is an azotæmic nephritis. Histologically nephritis acris resembles the nephritis symptomatic of bacterial infection. Where evidence has been obtained of a cause in examples not obviously symptomatic, the cause has been a bacterial infection.

Nephritis Acris Proper.—Nephritis acris can be separated into two divisions. In one division, acris proper, the inflammation is initially widespread and rapidly involves the kidney by extension. Examples have been obtained in an early stage before the appearance of granulation, in a stage of granulation, and in a late or chronic stage of sclerosis. In the early stage the clinical symptoms are those of a typical "acute hæmorrhagic nephritis." Our material representing this stage was obtained in years before the biochemical tests of renal efficiency were instituted. There was, however, clinical evidence of severe renal disturbance. The intermediate stage may be preceded clinically by the early, but more often starts insidiously.

In the more intensely inflamed examples the symptoms in the intermediate stage resemble those observed in the early stage, and death is due to renal inefficiency after a relatively short history. In the less intensely inflamed examples in the intermediate stage lipoid may be as abundant in the kidneys as in nephritis mitis. An insidious onset and the development of gross œdema are characteristic clinical features. Symptoms of renal inefficiency are present, but are seldom so striking as in the more intense type. The late stage is found on histological examination to follow only the less intense inflammation found among examples in the intermediate stage. Clinically it follows the milder illnesses of the intermediate stage or begins still more insidiously. In this late stage it is an azotæmic nephritis, accompanied or preceded by œdema. Cardiovascular hypertrophy, arterial degeneration, and consequent ischæmic nephritis make their appearance in the intermediate stage, almost without exception towards its close, and become more prominent and constant in the late stage.

Nephritis Repens.—The other division of nephritis acris is characterised histologically by the relatively focal nature of the initial inflammation and the slowness of its extension. No specimen of this condition has been found in the stages preceding sclerosis. Histologically the division has been separated into four types, which differ chiefly in diminishing degrees of intensity of inflammation and increasing slowness of extension of inflammation. These types have been distinguished more as a guide for future investigation than as a final classification. Taken as a whole this kind of nephritis is sometimes preceded at a long interval of time by an attack similar to that of the early stage of nephritis acris, but usually the terminal stage of uræmia is preceded by only trivial symptoms. With the exception of type (3), in which children and young adults are affected and renal regeneration is maximal, cardiovascular hypertrophy and consequent ischæmic nephritis are prominent features and are greatest in the most chronic type.

Histological and Clinical Nomenclatures.

Alternative histological and clinical nomenclatures have been suggested for the various forms of nephritis described.

Histological.	*Clinical.*
1. Pure or primary ischæmic nephritis.	Primary arterio-sclerotic nephritis.
2. Toxic nephritis.	
(1) Nephritis mitis in—	
early stage. intermediate stage.	Subacute hydropigenous nephritis.
(2) Nephritis acris in—	
early stage.	Acute nephritis.
intermediate stage.	Subacute azotæmic nephritis.
chronic stage.	Chronic ,, ,,
(3) Nephritis repens.	Insidious chronic azotæmic nephritis.

Macroscopic Appearances.

The macroscopic appearances in Bright's disease are usually not only unsafe as a guide to the underlying pathological changes in the kidney, but may even be misleading: thus, a "large white" kidney may either be an example of nephritis mitis or of the less intense type (3) of nephritis acris in the intermediate stage, and a "red granular" kidney may be an example of primary ischæmic nephritis or of the most chronic type of nephritis repens.

Distribution of Lipoid.

Considerable attention has been paid to the occurrence, amount, and distribution of lipoid in the kidney in all the different types studied, because so much prominence has been given to this histological feature in other classifications of Bright's disease. It has, in particular, been so linked up with the "nephrosis" of Volhard and Fahr and the "lipoid nephrosis" of Munk, that the occurrence of large amounts in the kidney or urine has come to be regarded as diagnostic of this mild form of nephritis. It is evident, however, from our investigation that such an attitude is most misleading. Large amounts of lipoid are present not only in nephritis mitis but in many examples of nephritis acris in the intermediate and late stages, and in some specimens of nephritis repens. Moreover, a variable amount of lipoid has been constantly found in all types of nephritis acris and nephritis repens, with the exception of a few examples of nephritis acris in the early stage and a few examples of the most chronic type of nephritis repens. It is obvious, therefore, that there is no definite association between the occurrence of lipoid and any specified type of inflammatory reaction in the kidney, nor can the presence of large amounts of lipoid in the kidney be the explanation of the clinical peculiarities of nephritis mitis.

Tests of Renal Efficiency.

In view of recent statements to the contrary (Beaumont and Dodds, 1925) Dr. Russell points out the usefulness of the routine tests of renal efficiency that have been employed in this investigation. These tests do not give a ready-made diagnosis, but serve as a valuable accessory to clinical observations. The discretion needed in their interpretation is illustrated by a list of extrarenal factors that can produce modifications of the results, and additions to this list will probably be made in the course of time. In Bright's disease the tests are of great help. They appear to be essential in distinguishing between nephritis mitis and the less intense type of nephritis acris in the intermediate stage.

Their second great point of application is in the separation of primary ischæmic nephritis associated with cardiovascular hypertrophy (clinical hyperpiesia), from the type of nephritis repens that is characterised by maximal cardiovascular hypertrophy. In ischæmic nephritis there is no impairment of renal function, whilst most examples of nephritis repens are seen first in the final stage of the disease when renal function is definitely impaired. The degree of impairment as estimated biochemically runs parallel with the amount of destruction found microscopically. But during the earlier stages of this type of nephritis repens that precede renal failure it has been seen that the focal nature and slow progress of the destructive processes in the kidney are compatible with normal renal function as judged by the routine tests. Hence the separation of primary ischæmic nephritis from this type of nephritis repens in the latent stage cannot be achieved by renal efficiency tests alone. Further work is needed to determine what other clinical criteria, if any, can be used in elucidation of this difficult problem.

BERLIN.

(FROM OUR OWN CORRESPONDENT.)

Psittacosis in Germany.

A PECULIAR disease has lately been observed in families which have newly purchased parrots. The usual symptoms have been high fever with unconsciousness, followed by a pneumonia which is peculiar in that discharge from the lungs is very small and the lesions spread in foci. Cardiac weakness appears early. The birds bought by the patients came from Brazil on a Hamburg steamer *Arcona*, and it is said that cases of infection by parrots have recently been reported in that country. Bacteriological research has shown that the disease is psittacosis, which has hitherto been almost unknown in Berlin. Anxiety has been aroused among the general public, and various kinds of illness in households where there are parrots have been ascribed to these unfortunate creatures. The Berlin Health Department, however, has stated that this nervousness is unfounded, since parrots which have not been recently purchased are harmless, and only those which have just come from Brazil need be regarded as suspect. None the less the Department condemns the custom of letting parrots peck sugar or other sweets from the lips of their owners. It is said that in the Zoological Gardens, where hundreds of parrots arrive every year from abroad, there has never been a case of psittacosis—probably because the Department insists on a control of zoological stores dealing with the sale of parrots and on a disinfection of the cages. At the present time parrots are being taken in large numbers to the veterinary college and to private veterinarians for examination, but so far only a few have been found ill. Among human beings there have been six deaths in Berlin, and also one death at Altona, which is beside Hamburg. The nurse and the doctor in charge of the dead patient in the hospital also caught the disease, but have recovered.

Measles in a Concentration Camp.

German peasants who were emigrating from Soviet Russia to settle in Canada were housed while passing through Germany in a concentration camp at Hammerstein in East Prussia. Already during their journey through Russia several infants had died, and in the camp a severe epidemic broke out affecting 192 children with 52 deaths. The nature of the epidemic was at first not quite clear, but it was soon ascertained that the disease was a severe form of measles with symptoms of septicæmia. A Government commission, including Prof. Friedemann, head of the department for infectious diseases of the Virchow Hospital in Berlin, was sent to the camp and reported that the disease had run an uncommonly severe course. This was due to the fact that the general state of the emigrants, and especially of the children, was very bad. They were underfed from the beginning, having received during their journey only bad bread, coffee, and tea; and the exertion of the long journey from Moscow to the frontier had made their state still worse. Similar cases had been seen, Prof. Friedemann said, during the late war, when the condition of children was rather like that of the emigrants. By order of the Government the Hammerstein camp was put under quarantine. Children received a diet rich in vitamins, and prophylactic

Public Health Services.

REPORTS OF MEDICAL OFFICERS OF HEALTH.

A SURVEY OF 1928.

WE have had the opportunity of summarising reports dealing with a great part of the population of Great Britain, and it may not be without interest to consider what evidence of progress in public health matters is to be gleaned from them. The year 1928, it may be noted in passing, was sunnier than its predecessor.

General Sanitary Measures.

Housing.—In most districts fewer new houses were erected, and there are signs that the demand for houses from families who can pay a reasonable rental is being gradually overtaken. A few districts are now beginning to take up slum clearance, but the new houses built are beyond the reach of the very poor. Amongst efforts to cater for the latter class Glasgow is to endeavour to provide an all-in 10*s.* house; and Stafford has earmarked 40 houses with three bedrooms on the municipal estate to be let to necessitous applicants at 9*s.* weekly including rates. Voluntary housing associations are taking a hand. A Lincoln society aims at providing 100 houses at 6*s.* 6*d.* per week (inclusive), and a York society at purchasing existing houses, renovating them, and letting them at weekly rentals from 3*s.* 6*d.* to 6*s.* 6*d.*, with Octavia Hill management. Perhaps the Cambridge society's contribution is the most noteworthy as it has actually provided 45 houses at rentals of 6*s.* 6*d.* (exclusive of rates) with a reduction of 6*d.* per week for each child of school age down to a minimum of 5*s.* Sheffield Corporation have set aside a number of houses for families which include an open case of tuberculosis. Other suggestions are the reconditioning of existing houses in order to provide accommodation for poor tenants evicted by slum clearance schemes, and national legislation for the prevention of the exorbitant rentals often demanded for houses-let-in-lodgings. Many medical officers speak approvingly of the Housing (Rural Workers) Act 1926, but as yet very little use has been made of its provisions.

Smoke Prevention.—The control of domestic smoke appears to be reaching a more practical stage. Several reports refer to the much more tarry deposit in residential than in industrial areas, owing to the less perfect combustion of the coal in domestic grates, and a much greater interest is being aroused in the production of smokeless fuel. It is even suggested that we are nearing the time when the burning of raw coal in the domestic grate will be prohibited. As regards industrial smoke, the new method of raising steam by the use of pulverised coal has evidently not been perfected yet, as several districts complain of the resulting nuisance from the emission of grit.

Rivers Pollution.—After the war many sewage disposal works suffered from the need for economy, but there are now signs of a greater desire to improve the condition of our rivers. More research is needed as to the best way of dealing with wastes from collieries, artificial silk, and beet sugar factories. On the other hand, it is now realised that the attempt to keep trade wastes out of the sewers has been in the past carried too far.

The *Health Education* of the public has received much more attention than in previous years. The circulation of the journal *Better Health* has now reached 268,000.

Food- and Water-supply.

Milk.—Better methods of milk production have been promoted by an increasing number of clean milk competitions and demonstrations in many counties, and more satisfactory premises are being provided under the Milk and Dairies Order, 1926. Systematic veterinary inspection of dairy cattle is a plant of slow growth, and in this matter the English counties lag behind the Scottish, but among the more populous counties Surrey has begun quarterly inspection, and Durham is making preparations for doing so. In many districts the percentage of tuberculous milk samples showed an increase in 1928, and there is no evidence that cows with udders affected and other signs of tuberculosis are being weeded out from dairy herds or notified by farmers at an early stage of the disease. The investigation of "outside" complaints of tuberculous milk has frequently ended in failure to trace the offending cow. The bulking of the milk from several farms at depôts in some cases increases the difficulties of these investigations. Several reports show that it is no easy matter to maintain a tested herd tubercle-free, and the county veterinary inspectors of Dumfries advocate double fencing and also the temporary segregation of new purchases to allow time for a possible incubation stage to elapse. In Scotland, too, we believe the risk of grazing tested herds on pastures which have been used by untested stock has been pointed out. The available quantity of graded milks has shown no rapid increase, and from several districts objections have come to the misleading designations at present adopted. Grade A is said to be regarded by the public as the highest quality of milk. Certified milk is usually about twice the price of ordinary milk, so perhaps it is hardly surprising to learn that the supply of this milk in the County of Dumfries already exceeds the demand. Apart from the London paratyphoid outbreak, considered to be due to infected cream, milk-borne infectious disease appears to have been less than usual in 1928, but a few small outbreaks of scarlet fever and diphtheria were traced to this source.

Water.—Most counties reported inadequate water-supplies in their rural parishes, and this creates especial difficulty in dairying counties. Even when we have obtained a national allocation of the available water, it will be difficult to provide a proper supply for many parishes at a reasonable cost.

Meat.—The new abattoir at Liverpool was begun during the year, and Coventry has obtained an ideal site for the same purpose. The improvement of imported meat will no doubt be promoted by the visit to the Colonies and the U.S.A. of the chief veterinary inspector of the City of London as the result of an invitation from the Governments of Australia and New Zealand.

Infectious Diseases.

Small-pox has been prevalent in many districts. In a large proportion of cases the introduction of the infection has been due to tramps. Few deaths were reported and the mild type is still breeding true.

Measles was epidemic in many districts, including London, during the year. The policy has been adopted in many districts of giving measles the preference over scarlet fever for hospital admission.

The use of antitoxin for *scarlet fever* is reported upon favourably, and several isolation hospitals claim to be discharging scarlet fever cases after 28 days without harmful results. In the Leicester hospital it is claimed that even better results are obtained by giving the antitoxin intravenously instead of intramuscularly.

There have been fewer cases of *encephalitis lethargica* notified, but the case fatality has been higher in many districts, and the unsolved problem of providing for the damaged survivors is referred to by many medical officers.

Glasgow had its first epidemic of *acute poliomyelitis* during the year. The acute cases coming to the knowledge of the health department numbered 112, mostly during July to October. This epidemic preceded the arrival of *influenza* (which was not prevalent in this country in 1928) from America during the early months of 1929.

The provision of hospital treatment for *pneumonia* is being urged more and more.

A few cases of *anthrax* have been reported, usually contracted from handling foreign hides, and Liverpool has put on record a series of cases successfully treated with serum without the excision of the malignant pustule.

Reports of *dysentery* came from Aberdeen, Manchester, Birmingham, Newcastle, and Staffordshire, and the suggestion is made that if the necessary bacterial examinations are made, it may be found that this disease is much more common in this country than has been hitherto thought.

Immunisation schemes against *diphtheria* continue to grow in number, and non-immunised isolation hospital staffs will soon be an exception. From most districts come complaints of delay in giving antitoxin, frequently because medical aid was not sent for sufficiently early.

A case of *undulant fever* was reported from Cardiff, and the subsequent discovery of *Brucella abortus* in several milk samples has raised the point as to whether milk-borne undulant fever may not be commoner than generally supposed.

Mosquito control is receiving more attention, and from Walton-on-Naze, Essex, came reports of a few cases of indigenous malaria, associated with the discovery of anopheline mosquitoes and the presence of ex-malarial subjects.

Maternity and Child Welfare.

The demand for more institutional lying-in accommodation is being gradually met and antenatal clinics are being established in connexion with all new maternity hospitals and homes. It is being realised that such clinics must be conducted by obstetricians. During 1928 an increase was recorded in the maternal mortality from sepsis in several districts. In some cases the appointed consultant obstetrician is being asked to investigate the cases of puerperal sepsis and the deaths from childbirth for the Ministry. A uniform international method of classifying maternal deaths in connexion with childbearing is much needed. Infant mortality is fast becoming a problem of early deaths from prematurity, &c., and of later deaths from respiratory diseases associated with measles and whooping-cough. The statistics we have given show that the chance for the young child (1 to 5 years) varies even more with the locality than infant mortality. Since the immediate after-effect of the war the birth-rate has not varied materially from year to year, so that the number of deaths in a locality at the age-period 1 to 5 per thousand births of the same year is a sufficiently reliable index of young child mortality. According to this index the young child mortality in 1928 was four times as heavy in Glasgow as in Leicester, and more than twice as heavy in the counties of Durham and Fife than it was in the counties of Somerset, Norfolk, Hampshire, and Northamptonshire. These are merely a few examples taken from our tables. Though opinions varied, there were many favourable verdicts as to the benefits derived from artificial light out-patient clinics, and frequently it was mentioned that the mothers who bring their children are favourably impressed by the results.

Other Municipal Schemes.

Tuberculosis schemes were hampered by the failure to secure early notification. Artificial pneumothorax is being more and more used in suitable cases by tuberculosis officers. As regards V.D. schemes, the percentage of default continued high. Many districts reported a rise in new cases, especially gonorrhœa, but it would be difficult to say whether this increase was due to a rise in incidence or to greater confidence in the treatment offered. On April 30th another rheumatism supervisory scheme was initiated—namely, at Croydon—with full coöperation of parents and teachers, but without provision for institutional treatment. It is much to be hoped that some provincial county borough will put in hand a complete scheme with provision for short stay and long stay cases in order that the possibility of preventing relapses and cardiac complications may be tried out.

MENTAL HOSPITAL REPORTS.

THE *East Sussex Mental Hospital* at *Hellingly* has published its report for 1928. On Jan. 1st, 1929, there were 1261 patients in the hospital. The recovery-rate for the year was 31·22 per cent., a lower figure than that for the preceding year on account of the unfavourable prognosis in a large proportion of new cases admitted. The death-rate was 6·82 per cent. There was a slight outbreak of influenza in March, and a rather more serious outbreak of scarlet fever in the autumn. The visiting surgeon performed 14 major operations, all of which were successful. The dental surgeon and the ophthalmic surgeon attended regularly, and submit special reports. They investigate thoroughly the teeth and eyes of all new patients, who receive also a searching physical examination supplemented by laboratory tests on the blood and urine. Parole was extended during the year, and at the end of it 55 men and 153 women were free within the grounds. Of the patients discharged 54 were first sent out on trial, 28 of them with a money allowance. The Swedish drill classes were again found to be of great benefit to the patients. A full account is given of the malarial treatment of 17 general paralytics. The results were not so good as in 1927. There is no organised occupational therapy, but about 14,000 new articles were made in the work-room during the year. The pathologist, in addition to carrying out the routine work of the institution—about 2000 tests of various kinds—also tests suspected tuberculous milk or organs for the public health authority. He has also found time for research into methods of analysis and into the causes and effects of mental disease. The urochromogen reaction has been found unreliable, but the complement-fixation test, elaborated on the lines of the Medical Research Council's No. 3 method, has proved very valuable. The Kahn test has been found less reliable than the Wassermann. The intestinal flora of patients has been studied and found abnormal in more than 80 per cent. Renal efficiency of general paralytics has also been investigated, and the malarial treatment has been found to throw a distinct strain on the kidneys and liver. The pathologist believes that more deaths of mental patients are due to renal poisoning than is commonly believed, and proposes to investigate this factor. The medical superintendent conducts a weekly clinic at the Princess Alice Hospital, Eastbourne. The shortage of female staff caused considerable anxiety. A social club for them has been organised, and everything possible has been done to improve their status. Three male and seven female nurses obtained their R.M.P.A. certificate during the year.

The report of the *Stirling District Mental Hospital* for the year ending May 15th, 1929, also appears somewhat belatedly. At the end of the year there were 964 patients on the register, 300 having been admitted during the year—a record number. In addition there were 24 voluntary patients. This increase put a heavy strain on the accommodation, which is unfortunately still burdened by a large number of mental defectives. The directors of the Stirling Royal Infirmary have asked the superintendent of the Mental Hospital to act as honorary visiting consultant to their new out-patient department for mental and nervous ailments. They have thus set an example to other provincial hospitals of Scotland. The recovery-rate in the institution was 37·44 per cent., and the death-rate 12·1 per cent. Autopsies were held in every case where permission could be obtained. There was an outbreak of influenza in the spring, but otherwise the general health was satisfactory. Modern methods of electrical treatment were applied to 135 patients, and the X ray apparatus was used for diagnosis in 22 cases. The dental surgeon visited weekly. An occupational instructress has been appointed and patients who cannot be occupied in any other way are taught rug-making, basket-, raffia-, and leather-work. The farm and gardens provided employment for about 200 male patients, and recorded a very good year. Nine nurses and four attendants obtained the R.M.P.A. certificate.

plants possess *the essential characteristic* of a living organism—namely, its power to grow and multiply (as Boycott himself agrees, p. 18); in other words, a living thing can produce more of itself by the incorporation and assimilation of less complex organic materials (food), using these to build up its own substance, this increase being followed in due course by division. In a living cell, there are plenty of dead things—inclusions, secretions, excretions, and the like; but these are all as dead as door-nails, so far as their power to increase independently of the living cell is concerned. Further, if, as Boycott admits may be the case, these invisible viruses are derived from ordinary living cells, that very fact would render it highly improbable that they themselves are distinct living entities. In any particular living thing, whether one of the lowliest cell-units, such as a bacterium, or a highly differentiated one, a congeries of which make up the body of a multicellular animal, we have not *the slightest evidence* that, in such a unit, there are contained lesser or simpler elements which subscribe to the definition of life. Indeed, apart from this, one has—a biologist particularly—an instinctive questioning, quite reasonable, as Boycott himself allows, whether it is possible for such minute particles as these invisible alleged organisms to be of sufficient size to contain the large aggregation of coördinated molecules necessary to constitute a unit able to exercise the wonderful functions of life. The *reductio ad absurdum* to which this "parasitic" view—as, essentially, it would be—would lead us is well shown by a consideration of Gye's theory about cancer, which implies that nearly all the cells of our body contain, normally, the invisible cancer-organism, a "foreign," intracellular, living element, which is only biding its time until the stimulation of some auxetic or adjuvant wakes it into activity! Even Boycott thinks this is an extremely unlikely idea.

And Boycott's own explanation is, I am afraid, equally improbable. The pity of it is that he does not see where many of his thoughtful and reasonable inferences inevitably lead! In these admittedly difficult cases, where we are dealing with minute quantities of substances which we cannot see, it is pertinent to bear in mind one of the essential postulates in connexion with the *vera causa* of the old logicians. Is the explanation reasonable, is it likely?

Now it so happens that I myself have devoted a considerable amount of research to this question and have come to the conclusion that the virus-diseases, and also malignant growths, are caused by non-living agents of the nature of ferments or enzymes, produced by the cells. As a matter of fact, I was the first to suggest this view and to bring forward, during a period of over five years, many observations and sustained arguments in favour of a comprehensive theory in explanation of the same. From the very first (1921) my view, in so far as the question of the transmissible property of the virus-diseases is concerned, was rendered, in my opinion, logically tenable by the very case which Boycott himself cites—namely, that of the bacteriophage of Twort-d'Herelle, which I regarded as an entirely comparable phenomenon. With regard to this, also, Boycott adopts a somewhat non-committal attitude. He merely says:

> "There are reasons for supposing that this agent arises in the bacteria themselves; . . . but the data are not conclusively against d'Herelle's view that it is really an independent parasite."

I believe the great majority of bacteriologists are agreed that this agent is a lytic ferment—even although this is not conclusively proved. In the case of virus-diseases, my theory assumes that the character of the normal blood-digestive enzyme has been altered by reason of the faulty vital activity of the cell, this pathological derangement having been induced at the outset by the infection with the virus—i.e., that particular modification of the normal enzyme in question. And it is very gratifying to see how Boycott is led to inferences which I have already drawn in certain of my papers. For instance, when considering the possibility that "fresh" virus may be made by each infected person or animal, he says that it is just possible that such diseases (he instances measles or distemper) were originally brought into existence by causes quite different from those which now maintain them. Similarly, I consider that these viruses have probably originated autogenetically, the pathological hæmetaboly having been induced in the first place by some outside cause, such as, in some cases, a very unusual manifestation or syndrome associated with an ordinary bacterial infection.[1] I may just mention two interesting possible examples, in a transitional phase, as it were, that is, developing at the present time, though these are still admittedly little more than speculations or notions, as Boycott puts it. They are encephalitis lethargica, and the virulent, devastating type of influenza; but here, too, lack of space precludes any consideration of them. Again, Boycott admits that if these viruses are the product of abnormal cell-activity, having once arisen, it is by no means impossible that some can arise *de novo*, nowadays, given the necessary conditions. (This is a very different thing, it must be borne in mind, from the creation of a new living organism, apart from an existing one!) And, indeed, as regards at least one type of stabilised, regular virus (if I may so put it), namely, typhus and its congener, trench-fever, the fresh origin of such virus by pathological hæmetaboly in its primary host, the louse, is, I venture to say, very much more than a mere possibility.

Just because it is so apparent from Boycott's article that the only alternative to a causal organism in the case of the virus-diseases and of cancer is a ferment, and because I was the first to put forward this view, as a result of my own work on the important function of normal blood-digestion and its various derangements, I have thought it worth while to trespass on your space.

I am, Sir, yours faithfully,

H. M. WOODCOCK.

Walton-on-Thames, Jan. 14th, 1930.

TESTS FOR MOTOR-DRIVERS.

To the Editor of THE LANCET.

SIR,—It is surely essential that a motor-driver should not be given a licence to drive till he has furnished a certificate that he is free from such a grave disability as to render him totally unfit to be a chauffeur. There are many men with very defective vision in one eye or partially deaf who are unaware of the fact, and many others who will not admit the defect.

The Road Traffic Bill, as amended in Committee (Clause 5, p. 6), accepts the applicant's *declaration* as to freedom from disability. In the interests of humanity, and for the safety of the public, I suggest that some *test* (neither severe nor expensive) should be insisted on for every applicant for a licence to drive a motor. A simple form might be filled in and signed by a doctor at a modified fee, paid by the applicant. The amount of the fee might be settled by the State. A re-examination and certificate need not be annual.

As one of the delegates I raised this point at the Conference on Street Accidents, convened by the Minister of Transport on Jan. 14th and 15th, which was supported by Mr. A. Hume Nicholl, Chairman of the London "Safety First" Council. The only arguments advanced against a test were on the score of expense and impracticability.

I am, Sir, yours faithfully,

D. A. COLES,

Chairman of Council of Industrial Medicine; Vice-Chairman of London "Safety First" Council.

Beckton-gardens, E., Jan. 17th, 1930.

---

[1] And, ultimately, it should be added, cellular autolysis, which is probably, in most cases, the end-result as regards the affected cells.

MUTILATING OPERATIONS.

To the Editor of THE LANCET.

SIR,—Having witnessed the circumcision of an infant of humble Jewish parentage many years since, the correspondence under the above title has interested me. In order to ascertain the details of the present manner in which the rite of circumcision is performed, I consulted a high authority on the subject, and his description, which I now quote, differs only from that at which I was present in the absence of antiseptic measures.

"The rite is not performed by a priest; the official is called the mohel, and he is always licensed by the Jewish authorities. It is always a particular kind of surgical knife which is used and is very sharp. The mohel with the wine in his mouth exerts suction when he takes the penis into his mouth; this is to draw blood, and it is usually done several times. But the actual stopping of the bleeding is by means of some astringent powder, or this mixture: sulphuric acid, 1 part; alcohol, 3 parts; honey, 2 parts; vinegar, 6 parts. The mohel is supposed to wash his hands in a solution of bichloride of mercury beforehand."

My friend states in a postscript: "Scriptural sanction exists for the rite only; its performance, —i.e., the details—is not mentioned; they have been gradually adopted."

I am, Sir, yours faithfully,
CHARLES W. CHAPMAN.
Wimpole-street, W., Jan. 16th, 1930.

COMPULSORY TREATMENT OF VENEREAL DISEASE.

To the Editor of THE LANCET.

SIR,—On behalf of the Executive Committee of the British Social Hygiene Council I should like to make clear the position of the Council in regard to the question of compulsory treatment of venereal disease, as certain of the remarks made by Dr. Sequeira in his letter published in your issue of Jan. 18th may give rise to misunderstanding. The Council holds no brief either for or against compulsory treatment of venereal disease. At its meeting on June 13th, 1923, it accepted the report of the Committee of Inquiry on Venereal Disease presided over by Lord Trevethin "as a document that can bring together all persons of goodwill in efforts to reduce venereal diseases." The report contains the following references to venereal disease:—

"We think that in the present state of public opinion any system of general compulsory notification of venereal disease would tend to concealment, and would prove a backward step."

"Notwithstanding what we have said above we are of opinion that it may well be that in certain areas special measures for the prevention of venereal disease would be justifiable, for example, measures for dealing with defaulters ....and we think that local health authorities who are able to make to the Ministry of Health a special case for some such special measure should be allowed, at any rate for some limited period, by way of experiment to carry out the measures they propose under the present system by which a contribution towards the expenses is made by the State. In this way there may ultimately be built up a body of experience of great value in determining future policy."

The position adopted by the Council was reaffirmed in the following resolutions passed at the meeting of Council held on July 5th, 1928:—

"The Executive Committee have received the information as to the Edinburgh Corporation Provisional Order, and in their view it comes under the conditions for experimental areas as suggested in the report of the Trevethin Committee, and in that sense they propose to watch the experiment with care, and do not propose to take any action";

and at the meeting of the Executive Committee held on December 2nd, 1929:—

"The Executive Committee recommend that in pursuance of the decision previously taken upon the Trevethin report, the Council should take note of the possible action of the Scottish local authorities in seeking additional powers for the treatment of venereal diseases, such powers to be for a limited time, and of an experimental nature."

I am, Sir, yours faithfully,
E. O. GRANT,
Secretary, British Social Hygiene Council.
Carteret House, Carteret-street, S.W., Jan. 21st, 1930.

THE FIRST ASYLUMS RESEARCH LABORATORY.

To the Editor of THE LANCET.

SIR,—With reference to the statement made by your Scottish correspondent in your issue of Dec. 14th, 1929, and Dr. Douglas McRae's support thereof, and with every respect and admiration for the Scottish effort in 1898, the claim to be first in the field cannot be sustained. The research laboratories of the London County Mental Hospitals, subserving the purposes of nine mental hospitals, accommodating 16,000 patients, came into existence in 1895.

I am, Sir, yours faithfully,
JOHN R. LORD,
Editor, "Mott Memorial Volume."
Epsom, Surrey, Jan. 20th, 1930.

To the Editor of THE LANCET.

SIR,—An annotation in your issue of Jan. 18th, entitled the First Asylums Research Laboratory, claims this title for the laboratory opened in Edinburgh in 1898. It may be of interest to point out that the Central Pathological Laboratory of the London County Council Mental Hospitals Department was established under the directorship of the late Sir Frederick Mott in 1895. It owed its inception to the report of a medical subcommittee of the London County Council, made in 1893, whose recommendation for the appointment of one pathologist of standing and position for the London Mental Hospital Service found a very vigorous advocate in Sir William J. Collins, the chairman of the subcommittee. It was decided to establish a central laboratory and museum at Claybury Mental Hospital, at that time only just finished. It was not until 1916 that the laboratory was removed from Claybury to the Maudsley Hospital. A member of the original staff recruited by Sir Frederick Mott in 1895, Mr. C. Geary, is still working in the laboratory.

I am, Sir, yours faithfully,
F. GOLLA,
Director, London County Council Mental Hospitals
Department, Central Pathological Laboratory.
Denmark Hill, S.E., Jan. 21st, 1930.

THE LATE SCARE IN BRIGHTON.

To the Editor of THE LANCET.

SIR,—I think it should be known among gentlemen of the medical profession who often send their patients here that there have been no further cases of illness in Brighton and Hove as a result of what has been called the "sore-throat scare." I have the personal assurance of the Medical Officers of Health concerned, Dr. A. Griffith, of Hove, and Dr. Rutherford Cramp, that no cases have come under their notice since the end of last year. The cause, as you may know, was traced to a certain milk-supply in a particular part of the county, which was fortunately traced to its source, the supplies stopped, and the danger removed. In no case, so far as it was possible to ascertain, was there any illness in the hotels, and this at a time when they were full to overflowing on account of the Christmas holidays.

I am, Sir, yours faithfully,
FRANK EVANS,
Chairman, Brighton and Hove Hotels and
Restaurants Association.
Jan. 21st, 1930.

glass—have shown in recent times not only that cells from the connective tissue may turn into blood corpuscles or migrating cells, but that real blood corpuscles, circulating in the blood, may migrate into the connective tissue and become connective tissue cells, real fibroblasts, builders of the connective tissue, and even fat cells, that help to build up the tissues of the body and to store up its energy. To my mind there is nothing so illustrative of the harmony of the body and the dominance of the organism as a whole over the cellular units as this interchange of functions this "interpenetration of all by all," which occurs wherever it is needed to maintain and secure the normal healthy state of all its parts. It is always the connective tissue—penetrating the whole body, carrying the nourishing blood-vessels, the lymphatics and the nerves, securing and guiding the chemical processes of the different organs, forming the supporting tissues (bone, cartilage, sinews, and ligaments)—which plays such a prominent part in this harmony of the organism and tries to secure it by constant efforts to adapt to the ever-changing environment.

The Problems of Senescence.

The problem of senescence is closely allied to the problem of growth. Why do we get old? Why has every animal a definite duration of life, varying little in a given species but extraordinarily different in different forms? Why is man among mammals distinguished by his extraordinary longevity, but why, after all, do we die? Of death we know nothing. We see it everywhere around is, but we do not know what it is, any more than we know what life is. Let us simply define death as the irretrievable loss of life and the definite change of the body into a corpse. Then we may say that for every living organism, for every plant and every animal, the price of life is death at the end. Of course we speak here only of natural death. When a body is crushed, burnt, or drowned, we are quite easily convinced that death follows, but even when we can exclude violent accidental death we see at the close of life that the energies become less and less, old age sets in, the movements become less frequent and less energetic, atrophy begins, and death is the end. "Natural death"—viz., the termination of existence due to uniform senescent atrophy of all the structures of the organism, leading to a uniform depression and ultimately to a simultaneous extinction of all the functions, is probably very rare. In actuality death is always in some measure accidental. An aged individual contracts pneumonia and succumbs to its effects, or a cerebral vessel is ruptured, or some other misfortune occurs as the result of a chance encounter. The same encounter, however, may have occurred repeatedly in the life of the individual without his ever having been conscious even of indisposition. Why has the final encounter a different issue? Simply because the underlying senescence of his tissues has rendered them more vulnerable. So, after all, death is the end of this general senescence of the tissues, and the real question we have to answer is why do we get old, and what is senescence?

Senescence is in the first place a general change of the body, not of a single tissue. The very old grow shorter in stature. At the age of 40 this diminution in height is already beginning, at 70 the average height has shrunk from 175 cm. to 160 cm. This decrease in stature is largely due to changes in the vertebral column, to stoop and to changes in the tissues. The roundness of youth has departed, the cheeks are sunken, the eyes have fallen far back, and the lips are drawn in. There is an atrophy of the tissues, especially of the connective tissues. The gait becomes shuffling, the old man drags himself cumbrously along; the power of his muscles and his control over the action of these muscles is lessened; there is an inferior coördination of his movements. The same phenomenon of atrophy shows itself in the digestive organs; the minute structures in the wall of the stomach by which the digestive juice is produced undergo a partial atrophy. The lungs are stiffened; the heart is enlarged, but acts more feebly than in the young; the walls of the arteries lose their elastic qualities; the germ-cells cease their activity altogether; the weight of the brain becomes less; the respiration is depressed; the body-warmth is diminished; in short, there is an atrophy in all the organs. So Metchnikoff, for example, sees the nature of senility in the single word: "atrophy." "On résume la sénilité par un seul mot: atrophie." Other scientists see the chief cause of senescence in the changes of the vascular system. According to Osler longevity is a vascular question; this view has been well expressed in the axiom that a man is only as old as his arteries. Others lay much stress upon the disharmonies, the imperfect adaptations of the tissues within us to the performances of the body as a whole. According to Mühlmann the fundamental nature of senility lies in that diminution of the surface in proportion to the bulk of the body which is characteristic of the old. He concludes that we become old chiefly because we do not have proportionately enough surface left. Further, he regards "physiological death" as attributable to the breakdown of the nervous tissues, especially in the brain. Lorand attributes physiological death to the failure of one or more of the organs of internal secretion. Savill refers it, as Osler did, to the progressive loss of elasticity of the arteries, with or without renal complication. In short, every part of the circle has been made to appear the origin of the whole.

Two scientists of the Institut Pasteur made, in 1912, a minute study of the tissues of a woman of 93 who had died in consequence of an acute illness of only 36 hours' duration. An unusual opportunity was here presented of ascertaining the condition of the organs of a very aged person without confusion by the special injuries due to a protracted illness. They found a great number of abnormalities, including widespread sclerosis, leucocytic infiltrations, hypoplasia of the glandular tissues and calcification of the blood-vessels, and the choroid plexuses in the brain and spinal cord. The suprarenal glands were hypertrophied. Any one of these abnormalities might have led, either directly or indirectly, to death. While death might have been attributed to the particular lesion immediately responsible, yet this would in fact have only determined the mode of death, and mortality was, as Robertson put it, actually ordained by the underlying senescence to which all of the lesions were ultimately attributable. So senescence is of a general nature; as Child formulated it, senescence is merely one aspect of development, and one alteration is the cause of another or of many others.

Those alterations may be purely chemical. For instance, the physiological value of nearly all the connective tissues is due to their colloidal nature. According to the interesting investigations of Heringa and Lohr, the collagenous fibrillæ are nothing but a gelification, an arrangement of polarised ultramicrones in a row, and connective tissue is a thread-forming gel. This colloidal structure may be altered by chemical changes in the surrounding fluids: the elastic fibres will lose a great deal of their elasticity when they are overcharged with calcium salts. A change in the lymph fluid may cause a considerable loss of the solidity and strength of the collagenous fibres. In old age the connective tissue loses its elasticity and strength; it becomes dried up and the amount of water is markedly lessened. The colloidal substance of the elastic fibres, the elastin is also changed by old age. It changes into elacin, which is far less elastic than the elastin of the young tissues. This elacin has a greater affinity for fixating the calcium salts and the iron salts and its elasticity is thereby still more modified. Thus the changes in the connective tissue elements are mostly of a colloidal chemical nature and irreversible.

If the symptoms of age are chemical and irreversible, is there no delaying of old age, no rejuvenescence? Of recent years much has been written about the "rejuvenescence" which follows the hypertrophy of the interstitial cells of the testes, consequent upon suppression of the gametogenic function by ligation of the spermatic ducts or the implantation of sexual glands from other and younger animals. The data presented by Steinach, however, or even those of Voronoff, indicate in animals so treated no evidence whatever of rejuvenescence in the sense of the delay or overcoming of senescence. The effect appears rather to be stimulative, possibly an acceleration of metabolism consequent upon the synchronous stimulation of several endocrine organs. It may very well be questioned whether such stimulation, the extent and force of which is not to be measured or regulated, in a senescent and exhausted organism may not rather be a disadvantage and even a danger. The evidence upon which Steinach appears chiefly to depend is a reawakening of the sexual instinct, a form of "rejuvenation" which is far from desirable in the aged. As might be expected, the outcome of the operation in some instances has been disastrous. Voronoff, on the other hand, assures us that in many cases he has obtained a marked and indisputable degree of real rejuvenescence by transplanting into aged animals sexual glands or one of the other endocrine glands. In the case of aged human beings, however, even his results seem to me to be still very doubtful.

According to Child, senescence is merely one aspect of growth. This is fully in accordance with the view of Minot, who years ago showed that senescence is not a feature of old age but shows itself, so to speak, already in early youth. Old age is simply the period of retardation of growth, of very slow decline, whilst senescence is at its maximum in the very young and its rate diminishes with age. Senescence depends on the differentiation of the cells, and natural death is the consequence of cellular differentiation. So we have to look at the problem of growth to understand the problems of senescence and old age.

The Problem of Growth.

The problem of growth may also be looked at from the chemical point of view. In the first place the rate of growth is not always the same, and periods of very slow growth are followed by periods of very marked acceleration. Thus the rate of growth during the first part of the period of gestation is very slow, but it is succeeded by an extraordinarily rapid accretion of tissue during the months immediately before and after deliver. Towards the end of the first year of extra-uterine life a definite slackening of growth occurs and this is succeeded by the relatively rapid growth of the third, fourth, and fifth years of life. Another pause or slackening ensues, to be followed by the energetic growth which accompanies adolescence (Robertson). Similar phenomena are exhibited in the growth of every animal. They led Minot to his thesis that the slackening of growth after the first peak of the growth curve is the beginning of the process of senescence.

It was pointed out years ago by Robertson that this phenomenon—a process which takes place at first slowly, later with greatly accelerated velocity and later still as slowly as it began—is seen in a number of chemical processes in which organic substances play a rôle; where the processes are what is called "autocatalysed" or self-accelerated. The fact that the reaction has occurred is, up to a certain point, a favourable condition for its further occurrence. Seen as a chemical process, the process of growth is autocatalysed; it develops accelerative agents as it proceeds. Robertson was therefore able to show that the process of growth, its acceleration and retardation, assimilation and decomposition, may be represented by the same curve and its course expressed by the same mathematical formula as an autocatalysed chemical process. In fact, it may be analysed as a distinct chemical reaction or a series of chemical reactions dependent on the velocity of the slowest reaction, which Robertson calls the "master-reaction." Not that the reactions of growth are simple reactions; the process of protoplasmic synthesis is exceedingly complex, involving multitudinous parallel, successive and independent reactions. Nevertheless, as Robertson pointed out, we may conclude that, in the chain of processes which culminate in the production of living matter, there is one reaction which is slower than the rest, so that the whole concatenated series of events waits upon this reaction, which may be called the "master reaction." So we could bring down the problem of growth, and of its velocity and acceleration, to the study of the "master reaction," which is probably of a very complex, multi-molecular type, and thus look at it from a chemical point of view, as Chodat did when he showed that in plants cellular multiplication, which of course underlies the process of growth, is autocatalysed. According to Chodat the catalyser is the living cell itself, but in animals the processes of growth and cellular multiplication are far too complex to be explained so simply, and we have to look for other processes by which the growth curve may be influenced. When we try to look at the problem of growth from this chemical point of view, to study the master reactions, and to look for retarding and accelerating influences, we see that a vast field of interesting research lies barren, and that in this way we may get a better insight into the process of growth and thence into the histological basis of health than from any other point of view.

To give a curious example, we see, as Gurwitsch has shown, that multiplying cells send out peculiar rays of a very short wave-length by which other cells are induced to divide and to multiply themselves, so that the process of cell-division is catalysed. We see that the accessory food factors of Gowland Hopkins, the vitamins of Eykman, have a distinct influence on the rate of growth. For example, the fat-soluble accessory contained in butter is essential for the growth and reproduction of animals (Hume, Masing). Adult rats are able to withstand its absence from their diet for over a year without loss of weight, but if previously, in the growth period, they have been confined to a diet deficient but not altogether lacking in it, then subsequently when they are nearly adult deprivation causes, after some delay, a sudden decline of weight and ultimate death from apparent inanition or from intercurrent disease. When young animals which have hitherto received normal nourishment are suddenly deprived of this factor, they continue to grow for a considerable period, but growth cannot be sustained and the arrest of growth is followed by progressive loss of weight (Robertson). The water-soluble accessory factor, the original vitamin studied by Eykman, which is present in leguminous seeds and in the germ of cereals (from which it was secured in crystalline form by Jansen), has the same properties. It is essential for the growth of young animals and children, and indeed the effect of its deficiency in the diet is much more rapidly evident than the effects of deprivation of the fat-soluble accessory. But not only is growth suspended; other abnormalities too are displayed when it is absent—e.g., cessation of the growth and multiplication of the germ-cells, atrophy of the lymphoid tissues and of the thymus gland, and diminution of the number of lymphocytes in the blood. We may safely say that all the known vitamins play an important part in the acceleration and retardation of growth, in the formation of hormones, in short as catalysers in the chemical processes of the body. In the same way we may attribute to the formation of autocatalytic substances the stimulating effect of certain hormones upon the growth of certain tissues—viz., those which give rise to the secondary sexual characters.

It is of great interest to study the effect of nutrition upon growth from the chemical standpoint. That good food is necessary nobody will ever deny, but we must not overrate the influence of food upon the essential factors of growth. Many animals are known to take no food during metamorphosis; they therefore feed on their own tissues, and get smaller during development. Even in starvation the nutrient level is never at zero, and cells possessed of a very low nuclear ratio—i.e., not differentiated—may actually multiply at the expense of the other tissues of the organism, as when a wound heals or regeneration occurs in a starving animal. Even in starvation Nature strives by all possible means to maintain the dynamic equilibrium of the body. The cells become smaller, but the relation between the nucleus and the cytoplasm, the nuclear ratio so important for the metabolic processes inside the cell-body, remains the same as long as possible. When it is altered it becomes as in periods of intense growth, so that we can speak of a rejuvenescence of the organism analogous to the condition in the embryo, where the cell-body is likewise small in relation to its nucleus. Thus we can understand the interesting fact, first demonstrated by Morgulis, that there is in different animals a great acceleration of growth-rate after a period of inanition. If, as Morgulis pointed out, at a certain period of growth in salamanders the proportion of food converted into protoplasm was 26 per cent., after starvation and readmission of food it rose as high as 73 per cent. Kahan, a Russian investigator, found (I quote again from Robertson) that rabbits after 17 days of inanition, when they had suffered a loss of 31 per cent. of their body-weight, gained 56 per cent. in weight on a diet even less sufficient than that which could maintain them in a state of equilibrium under normal conditions. In other words, a diet which before barely permitted maintenance becomes, after a period of starvation and even at the same body-weight, a diet which permits growth. Retarded individuals in any random group of children generally exhibit a late acceleration of growth; in this connexion we can point to the compensatory overgrowth which succeeds the postnatal loss of weight in infants. Furthermore, those organs which are most essential to the preservation of existence are those which suffer least extensively from the deprivation of food, as, for instance, the heart and the central nervous system. Their autocatalyst level rises at the expense of the less important organs and cells. Thus the problem of growth and nutrition brings us to the problem of the differentiation of the tissues and the cellular units.

The discussion of the histological basis of health has therefore brought us gradually down from the general principles by which our organism is governed—harmonious development, and the harmony in the functions of the adult and its alterations by senescence—to the details of nutrition and to the differentiation of the cells and tissues.

STANDARD RATINGS FOR X RAY APPARATUS.

WE have received from Messrs. Watson and Sons (Electro Medical), Ltd., a catalogue entitled "High Tension Transformers." It is a booklet of 47 pages, a third of which is devoted to the simple physics of modern X ray apparatus, the remainder describing the large variety of X ray sets made by this well-known firm. The principle and construction of X ray transformers are briefly described, and the rectification of the current from high tension transformers, more especially by valve tubes, is also dealt with. The importance of the testing of transformers is emphasised, and it is with pleasure that we notice that this firm has adopted the standard ratings for X ray transformers proposed by the British Electrical Standards Association to which we referred recently (Dec. 28th, 1929, p. 1374). The current from a transformer is alternating in character and an effective value which takes an account of this fact is adopted in the standard specification. The current from an X ray set complete with rectifier is, however, unidirectional. For sets of this kind Messrs. Watson and Sons have adopted ratings similar to those proposed for X ray transformers except that the effective value of the alternating current of the latter is replaced by the reading afforded by the milliammeter when the set is working under the specified conditions. The catalogue is replete with diagrams and excellent photographs of X ray apparatus.

EARS OF CORN EXTRUDED THROUGH THE CHEST WALL.

THE LONG ARM OF COINCIDENCE.

To the Editor of THE LANCET.

SIR,—In your issue of Jan. 11th appeared the story of a child of 3½ years in Staffordshire who had sniffed into his lungs a one and a half inch long grass seed, and after considerable travail had delivered this through an abscess in the right scapular region. In the *British Medical Journal* of the same date appeared a report of a similar case in which a child of 9 months in Hertfordshire had inhaled a one and a half inch grass seed and had got rid of this through its right scapular region. How few of your readers will have seen or heard of such a case, and how unlikely that two such cases should have been under treatment in September last year, and should have been brought to the notice of the medical profession in the same week!

I am, Sir, yours faithfully,

PERTINAX.

Mr. Vincent Patrick, who (with Dr. E. H. Coleman) described the case in our own columns, sends us a letter he has since received, making the third which has come to his knowledge. This letter runs:

> Dear Sir.—I have taken the liberty to write to you about the boy that swallowed the grass ear, as my son, aged 17, swallowed one 16 months ago. He was very ill, but as he did not tell us he had swallowed the ear, a doctor treated him for rheumatic trouble. After he had been in bed a few days he had a swelling at the bottom of his left lung, and of course I put hot fomentations on, as I thought it was an abscess. While I went downstairs to get some water to wash him, he got out of bed and, looking over his shoulder in the looking glass, saw the swelling, which he pressed, and the grass burst out right to the other side of the room. The smell of the stuff that came away was terrible. I had to put a handkerchief over my nose. He now has a nasty hacking cough sometimes at night. I have got the grass in a bottle, but it has broken in two. The grass ear must have passed right through his left lung.
>
> I remain, yours respectfully,
>
> Mrs. X——.

An ear of rye grass was shown to the Clinical Society of London nearly fifty years ago (THE LANCET, 1882, i., 350) by the late Sir Rickman Godlee. This ear had been "swallowed" by a child two years old, and 43 days later made its exit through the back between the sixth and seventh ribs, three inches from the spine on the left side. He thought the grass had probably entered the œsophagus and not the trachea, the cough being due to some accompanying pleurisy. At the same meeting Mr. R. W. Parker related the case of a child in whom a swallowed piece of grass emerged through an abscess in the left side, the contents of which had a distinct fæcal odour; and Mr. Golding Bird mentioned an ear of rye grass covered with pus which had been brought to him by a friend with the story that it had been swallowed by a girl, eight years of age, who suffered for a year from illness believed to be phthisis, but who recovered after the ear of grass had presented in an abscess under the left breast.

THE BRITISH RACE IN MEDICINE.

A LECTURE delivered recently by Dr. R. O. Moon, under the auspices of the People's League of Health, proved of interest to the audience because the lecturer, while narrating historical facts concerning many great names, was able to point to the characteristics which were displayed by the various discoverers connected with British medicine. The great Sydenham emerges as a very British type. Of learning, as such, he seems to have had a deep distrust, but on the necessity for close personal observation, and for collating the phenomena of disease with those of natural history, he was emphatic. He classified great diseases and made sound pathological deductions, but seems to have entirely overlooked Harvey, who had published the *De Motû Cordis* when Sydenham was only four years old.

DETECTION OF POISONS BY THE SPECTROSCOPE.

THE delicacy of the spectroscope as a method of revealing traces of elements far too small to detect by any of the usual chemical tests is well known, so little as 10^{-9} gramme of sodium being revealed by this means. Emission spectra have come to be recognised as the most reliable criteria for the identification of elements where only small quantities of material are available. The use of absorption spectra for the detection of alkaloids in solution was described so long ago as 1903 by Dobbie, but this aspect of the subject has only comparatively recently received attention from toxicologists. The significance of absorption spectra has lately been much in evidence in connexion with work on vitamins. The publication of a 17-page pamphlet entitled "The Detection and Investigation of Poisons by Spectroscopy," by the firm of Adam Hilger, is therefore timely. The subject matter is divided into three sections entitled Applications, Equipment, and Methods of Working. Under the first heading are given specific examples of the employment of the method with reference to original papers. The section on Equipment gives particulars as to cost of outfit, while a brief description of working details is given in the last section. A perusal of the pamphlet will impress the reader with the great potentialities of the spectroscopic method of examination when placed in the hands of competent workers.

TREATMENT OF CANCER AT THE BRISTOL ROYAL INFIRMARY.

To the Editor of THE LANCET.

SIR,—In view of the unauthorised and misleading statements which have appeared in certain sections of the lay press the Faculty of the Bristol Royal Infirmary would be glad if you would allow them to state very briefly the true position with regard to the treatment of cancer here. A considerable amount of research has been carried out, both clinically and in the laboratory, and special beds have been set aside for the study of cancer. A number of patients have been relieved, in some cases to a very gratifying extent, by lead compounds and other methods of treatment, but some unfortunately show no improvement, and no claim to have achieved a cure has ever been made. Details have appeared, on more than one occasion, in medical publications.

I am, Sir, yours faithfully,

R. C. CLARKE,

Hon. Secretary to the Medical Faculty,
Jan. 15th, 1930. Bristol Royal Infirmary.

A PERMANENT HOME FOR CHRONIC INVALIDS.

THE search for an inexpensive permanent home suitable for chronic invalids, especially those helplessly crippled by rheumatism or totally incapacitated by poliomyelitis or disseminated sclerosis, is often fruitless. Our attention has been called to one recently established by two registered nurses at The Oaks, Malden-road, New Malden, Surrey (Malden 1264). The home is five to eight minutes' walk from Malden Station, whence trains leave for Waterloo every five minutes. At present accommodation is available for nine patients, divided into one room with three beds, two rooms with two beds and two single rooms. There is a common room for the use of patients who are not bedridden and an attractive garden. Patients can choose their own medical attendants, arrangements being made for those who come from a distance. The fees are from 2½ to 6 guineas weekly, excluding medical fees and personal laundry. Patients' friends are admitted at any time during the day, and can be accommodated for short periods.

SEROLOGICAL DIAGNOSIS OF MALIGNANT DISEASE.

THE Lega Italiana per la lotta contro il cancro offers a prize of 15,000 lire for an original paper, written from a critical and experimental standpoint, on the Value of Serological Methods in the Diagnosis of Malignant Tumours. The paper will be judged by a committee of three, appointed by the President of the League. The papers must be typewritten, anonymous, and sent in duplicate to the headquarters of the League (Rome (33) Via Triboniano, presso Piazza Cavour, Casa dol Mutilato) in a closed envelope, bearing a motto on the outside. The same motto must be written on another closed envelope containing particulars of the author's name, address, &c. Papers must reach the above address not later than June 30th, at midday. The League reserves the right to publish the winning paper, for the first time, and in Italian, in its Bulletin.

COLONIES FOR MENTAL DEFECTIVES.—The Board of Control, with the approval of the Minister of Health, have appointed a committee to consider and report what are the essential structural requirements of a complete colony for mental defectives of all types and to what extent the cost could be reduced by the adoption of semi-permanent or temporary buildings or other new methods of construction, having regard to the comparative cost of maintenance as well as the initial capital expenditure involved. The Committee is constituted as follows:—Mr. Walter Hedley, K.C., Recorder of Newcastle-on-Tyne (Chairman); Mrs. F. Rose Davies, J.P., Alderman, Glamorgan County Council; Miss Clara Martineau, J.P., Member of the Birmingham City Council; Sir George Oatley, F.R.I.B.A.; Dr. A. Rotherham, Commissioner of the Board of Control; Mr. A. Scott, A.R.I.B.A., Chief Technical Officer, Ministry of Health; Sir Lindsey Smith, J.P., Chairman of the Board of Governors of Holloway Sanatorium; and Dr. F. Douglas Turner, Medical Superintendent of the Royal Eastern Counties Institution, Colchester; with Mr. H. J. Clarke, of the Board of Control, as Secretary.

A Contribution
TO THE STUDY OF THE
TREATMENT OF EPITHELIOMA OF THE TONGUE BY RADIUM.

Being a Hunterian Lecture delivered before the Royal College of Surgeons of England on Jan. 29th, 1930,

By G. E. GASK, C.M.G., D.S.O., F.R.C.S. Eng.,
PROFESSOR OF SURGERY IN THE UNIVERSITY OF LONDON.

In presenting this study I wish to say that it is really a contribution from the members of the Surgical Unit of St. Bartholomew's Hospital, of which I am the mouthpiece. We feel that the time has come to consider, more in detail than was previously possible, the relative value of treatment of carcinoma of the tongue by the old-established method of surgical excision and the new, much hoped for, rather spectacular, and not yet fully established treatment by radium. The amount of information at our disposal is still too small to arrive at definite conclusions, but it is important to consider what there is, seeing that in a short time the amount of radium in the country will be considerably increased. Following the Thanksgiving Fund for His Majesty's recovery and the foundation of the Radium Commission, a number of national radium centres are about to be started in the University medical teaching centres of England, Scotland, and Wales, so that in a short time we may expect a great stimulus to the radium treatment of patients suffering from cancer, and among these there are sure to be many suffering from cancer of the tongue. It seems to us, therefore, an opportune moment to take stock of the knowledge which is now available, to table the results obtained by surgery, and to scrutinise with care and without fear or favour the results and methods of radium treatment.

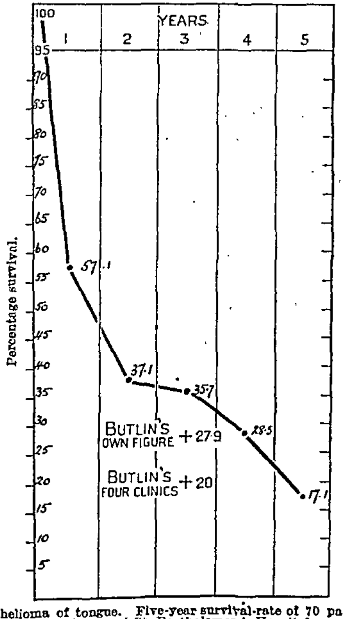
Results of Surgery.

We have tried first to reach the approximate figure of the cures of cancer of the tongue obtained by surgery, so as to have a fixed point for comparison between surgery and radium therapy. Operations for removal of the tongue have been performed by surgeons now for many years, and we ought to be able to give accurate detailed figures for the results of surgery in all the different phases of the disease. Unfortunately, the medical profession has appeared unbusinesslike in the matter of compiling statistics, and slow in adopting follow-up schemes, with the result that it is difficult to find a large number of conclusive figures. Statistics are cold, heartless, things, which do not recommend themselves to optimists, but it is necessary to inflict some of them on you.

Statistics of St. Bartholomew's Hospital.

In 1922 a follow-up department was started at this hospital for the purpose of tracing the end-results of all patients suffering from cancer of the tongue. The results are shown on the accompanying graph. Included in this series are all those patients who were deemed operable, and were, in fact, operated on in one way or another by the various surgeons attached to the hospital. The results of the varying types of operations are not differentiated, as it was thought that the figures wanted were those that showed the value of surgery as a whole. Three years is not a long enough period to judge of any form of treatment of cancer, so only those patients have been included in this review who might have survived five years from the date of their original operation. Of these there were 70, of which only 12 remained alive and well and free from recurrence at the end of five years from the date of their operation. That is to say, there was a survival-rate of 17·1 per cent. (It is interesting to note in passing that if the period of observation had been continued for longer than five years the percentage of so-called "cures" would be still further diminished, for of the patients noted above as remaining well for five years three showed recurrences at the close of six years, and two at the end of seven years.)

Mr. R. F. Phillips, Luther Holden Scholar, who is now working on the end-results of patients suffering from buccal carcinoma (including carcinoma of tongue, floor of mouth, cheek, lip, tonsils, and palate), has supplied the following interesting figures which may later throw some light on the problem being studied. He holds that buccal carcinomata show degrees or grades of malignancy, which may be measured and foretold by their histology. Following Broders's[1] work, Mr. Phillips has examined the histology of the tumours from a large number of patients who have been treated at St. Bartholomew's Hospital between the years 1924 to 1927. These are divided into four grades, according as they show cells approaching the normal tissues or differing greatly from the normal and approaching the embryonic type. Thus, Grade 1 contains those cases which show much cell-nest formation and few mitoses, and Grade 4 those cases which show no cell-nest formation and much mitosis: whereas Grades 2 and 3 are intermediate.



Epithelioma of tongue. Five-year survival-rate of 70 patients operated on at St. Bartholomew's Hospital.

The 159 patients observed fell into the following grades:—

Cases and Percentage.

Grade 1	21	(13·2)	Grade 3	50	(31·4)
„ 2	73	(45·9)	„ 4	15	(9·4)

---

[1] Broders, A. C.: Grading of Carcinoma and Practical Application, Minn. Med., 1925, viii., 736; and Epithelioma of Cavities and Internal Organs of Head and Neck, Arch. Surg., Chicago, 1925, xi., 1.

Thus, it will be seen that the largest number falls into Grade 2 and the smallest into Grade 4, the most malignant category. Mr. Phillips next worked out what happened to the patients in these various grades and tabled the survival-rate in each. He believes that the prognosis or chance of survival is definitely related to the type of growth. Thus, he finds that the survival-rate in

Per cent.
Grade 1 is 36·4 }
,, 2 is 18·2 } at the end of three years.
,, 3 is 8·0 }
,, 4 is 0 (all dead).
Number of patients followed, 90.

It should be interesting to find out whether any of these grades are more or less susceptible or sensitive to radium. There is some evidence to support the view that the cases falling into the first group—namely, those showing marked cell-nest formation with little mitosis, are less sensitive to radium than those highly malignant types in Group 4. More work is required, however, before this can be stated as proved.

Selection from Published Sources.

The results of surgery obtained by us at St. Bartholomew's Hospital are so bad that it seems only right to compare them with a selection taken from the published sources. Naturally, one's mind turns first to the publications of Sir Henry Butlin,[2] a Past-President of this College, who had the highest reputation for his work on cancer of the tongue.

Butlin gave a list of 197 cases of carcinoma of the tongue, which comprised all those operated on by him, the first of which was in 1881 and the last in 1908. Of these 197 patients, 55 lived for three years or over without recurrence—that is, he had a survival-rate of 27·9 per cent. at the end of the three-year period. The recent St. Bartholomew's Hospital figure at the end of three years is 35·7 per cent., so that there is not much difference between the two.

Butlin also quoted the combined figures of his own and three other clinics—namely, those of Whitehead, Krönlein, and Kocher. The combined figures of these four clinics showed a survival-rate of 20 per cent. at the end of the three-year period.

The survival-rates given by a number of other authors are: 18 per cent. by Capetti; 26·6 per cent. by Caird; and 14·3 per cent. by Cobb and Simmonds.[3]

The Mayo Clinic figures for the years 1910 to 1922 show a survival-rate of :—

30·8 per cent. at the end of 3 years.
24·4 ,, ,, 5 ,,
4·25 ,, ,, 10 ,,

A general survey of these figures, showing the results of operations for cancer of the tongue taken from clinics in various parts of the world, leads us to the conclusion that the best we can expect from surgery is a survival-rate of from 20 per cent. to 25 per cent. This is the basis on which the results of radium treatment can be compared.

RESULTS OF RADIUM.

At this point it is appropriate to turn back again to consider an almost prophetic utterance made by Sir Henry Butlin[4] 21 years ago, shortly before his death.

> "At this moment, it would scarcely be too much to say that the air is charged with the emanations of radium. We are told that epithelioma of the tongue can be cured by radium. Had I been asked my opinion on this question a month ago, I should have said that, although two or three people in different parts of the world have claimed this power for radium, the general belief is that rodent ulcer is the only variety of malignant disease which radium is competent to cure. And I should have added that the only case of epithelioma of the mouth in my own practice to which radium had been applied (by the most skilful man with the best material) had ended disastrously. But I have, within the last few days, seen a case in which a typical epithelioma of the inside of the cheek is so much better, under the application of radium, at the end of four months, that it looks as if it would be quite cured. And this had apparently been accomplished without inflammation or sloughing or profound ulceration of the disease. I understand that the radium in this case was applied by means of the disc. As this epithelioma was about 1¼ inches in diameter and ulcerated all over, when I saw it four months ago, there seems no reason to doubt that small epitheliomata of the tongue may be removed by radium, probably with a better scar than would be left by any other efficient agent. But, having said this, it must not be forgotten that the removal of the primary disease is only part of the cure of epithelioma. Even the smallest, the youngest, and apparently the most insignificant epithelioma of the tongue is capable of affecting the lymphatic glands, as the cases I have related show. So that, unless radium is discovered to possess a far-reaching influence, spreading from the seat of the primary disease to the associated lymphatic glands, I am afraid that the surgeon must still occupy an important place in the treatment of epithelioma of the tongue."

Is not this a very remarkable forecast? It is humbling to realise that 21 years have passed since it was made, and that progress has been so lamentably slow. What one would like to be able to do now is to state the results of the treatment of epithelioma of the tongue by radium and to compare them with those obtained by surgery. At the present time these figures are too few and too recent to be of any great value, though it is greatly to be hoped that in a few years adequate and reliable figures will be available. The Radium Commission has adopted the policy of asking all the national radium centres which are being started to keep their records on uniform case sheets. These records in due course are to be collected and analysed, so that in the near future we may expect to have at our disposal a very large number of figures which should prove of great value.

There are, however, a few figures which have been published which are worth looking at. G. E. Birkett,[5] of the Manchester Radium Institute, who has done splendid pioneer work with radium, states :—

> "There are no five-year figures available in this country, but continental workers report about 45 per cent. of five-year cures as regards the primary site, and 20 per cent. of absolute cures."

I gather that the figure of complete cures over a three-year period from the Manchester Radium Institute is 22–50 per cent. This result is not incomparably better than that obtained by surgery.

Roux-Berger and Monod,[6] from the Radium Institute of Paris, report that during the six years 1920 to 1925, inclusive, they treated 287 cases of epithelioma of the tongue, out of which number 77 were cured. By "cured," they say they mean those patients who were free from disease on Feb. 1st, 1927. This gives a percentage of cures of 26·8, or if a three-year period is taken on a total of 120 cases, 21·6 per cent. This is not as high a percentage of cures as one might have hoped for, and again does not appear to be much better than the results of surgery.

Radiumhemmet in Stockholm reports that, from a list of patients treated during the years 1921 to 1926 (inclusive), 14 are alive and well out of 46 treated; a survival-rate of 30·4 per cent. This again seems to be no better result than that obtained by surgery. At the same time they report a 78·3 per cent. survival-rate of cases of epithelioma of the lip at the end of two years.

[6] Radiophysiologie et Radiotherapie. By Regaud. Vol. i., fasc. ii., Paris, 1928.

It is admitted that these figures are few in number and recent, but it looks as if the final results are not startlingly better than those obtained by surgery. There are, however, some qualifying remarks to be made a little later.

A SURVEY OF THE WORK OF THE SURGICAL UNIT, 1928–29.

We now present to you a detailed account of those patients treated in the Surgical Unit during the years 1928 and 1929. The number is not great, but a careful study of even a small number of patients cannot fail to be of value, and certain deductions can be drawn.

The method of treatment of the primary growth of the tongue has been by radon seeds, of a strength varying from 1·5 mc. to 3 mc. The seeds were encased in platinum capsules of a thickness of 0·3 mm., increased later to 0·5 mm., so as to minimise burning. On an average the seeds were left in for seven days. The reason why radon seeds were used and not radium needles was, in the first instance, merely one of convenience. Seeds were available at a time when suitable needles were not, and further it appeared to us that seeds were more adaptable than needles for placing in the folds and crannies of the mouth. We hold no brief for radon as opposed to radium, but we only want to find out the truth. There seems to be an impression that the emanation is not as effective as the element on account of the rapid disintegration of radon. Physicists say that there ought to be no difference between the action of radon and radium, provided that a suitable dose be given. Our own observations tend to bear this out.

The glands in the neck have been treated in the main by a barrage of radium needles, inserted at the same time as the seeds in the tongue and arranged according to the accompanying diagram. Needles containing radium element were used in this instance as it was desired to irradiate large areas of tissue containing lymphatic glands. The needles were inserted by puncture and, as far as we know, no damage was done to any of the structures in the neck. The advisability of using needles for treating the glands of the neck, or of dissecting the glands, or of combining surgery with radium treatment, will be discussed later.

Deductions Drawn from an Analysis of 30 Cases.

There are certain points arising out of a close study of these figures which are worthy of comment. In the majority of cases the tongue has been materially affected by the action of the radon seeds; in the majority the original primary tumour or ulcer has disappeared entirely in the course of a few weeks and the tongue has been left a mobile useful organ.

In one instance (Case 10) the carcinoma was, as far as we could see, entirely unaffected by the action of radon seeds, and later the tongue was excised. The reason why this epithelioma did not react to the rays is unknown to us. Perhaps it was non-sensitive to radiations. Histologically it fell into Group 1 classification, that is to say, it showed well-marked cell-nest formation. Perhaps the seeds were below strength; perhaps they were not placed accurately. In another instance (Case 25), a woman with an easily accessible ulcer close to the tip of the tongue, the carcinoma was not materially influenced by the action of the radon seeds and her tongue has been excised. The histological findings show that she also falls into the Grade 1 classification. Perhaps these cases might be used as an argument for the use of the element rather than the emanation.

The question of the non-radio-sensitivity of some tumours is very puzzling and requires investigation. It emphasises the fact that we are still very much in the dark about the whole problem, and that our treatment is still empiric. There were six other patients in whom the tongue was not healed by the treatment. These may be accounted for in the main by the fact that the growths were extensive and infiltrating. Quite a number were advanced and inoperable. We were not trying to produce a unique record of cures, but endeavouring rather to see what could and what could not be done.

One thing that is perfectly clear is that if the primary growth is treated early it can be made to disappear by the use of radon in the great majority of cases, leaving a useful mobile organ. We know also from the work of others that the same result may be obtained by radium element. I repeat that we are not arguing here in favour of the emanation against the element, but merely trying to record the facts as we have seen them.

The second point is that the patients who have died, and there have been ten—a third of the total number—have been advanced cases of carcinoma, cases which would have been classed as inoperable surgically, cases which had in all probability dissemination of disease at the time of treatment. This is to emphasise once again the point that treatment, if it is to be successful, must be before the disease is advanced and disseminated.

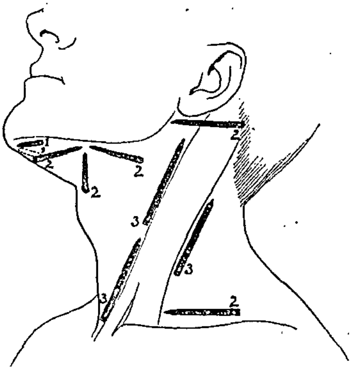

Diagram showing method of irradiating lymphatic areas with radium needles. (Figures refer to milligrammes of radium element in needles.)

The third point that arises prominently from these figures is the unsatisfactory state of our knowledge of the right method of treating the lymphatic glands. It will be noted that the method of treatment adopted by us has varied. In the majority of cases the method of irradiation by radium needles inserted through punctures in the skin has been used. This method has appeared to us to be satisfactory when applied to the lymphatic gland areas in cases of carcinoma of the breast. But it has not turned out uniformly satisfactory for the glands secondary to carcinoma of the tongue.

In seven instances, Nos. 6, 9, 14, 20, 22, 24, and 27, the glands have not responded. Six of the patients have died, and one—Case 27—will probably die soon. In a number of patients regression or disappearance of the glands has been noticed after irradiation, and, although this is encouraging, it is not proof that the glands were secondarily infected with carcinoma and that they were sterilised by radiation. It is well-known that glands which are palpable clinically are often shown histologically to be inflammatory and not carcinomatous. We have no direct evidence that radium puncture does actually sterilise carcinomatous glands. In some instances the glands have been dissected, and it is possible that this should be, at any rate for the present, the method of choice.

toxin combining with a tissue. The experiment of Pasteur, showing how a normally immune hen can be inoculated with disease if her temperature is lowered (or if the rate of atomic vibrations is lowered) may be an illustration of such a hypothesis.

Immunisation has been considered up till now merely as a biological phenomenon. I want to show you to-night how immunity, and even specific immunity, can be acquired from non-organic antigens.

A Few Experimental Facts.

I am anxious you should feel the solid rock of facts underlying this far too speculative discourse. Sparteine sulphate, in a dose of 7 mg. injected into an animal of 100 grammes in weight, is always fatal. Now if a higher dose, say, 10 mg., of the poison is mixed within the syringe with 5 c.cm. of mineral water from La Bourboule or Mont Dore springs, the animals do not present any symptom of intoxication. But if you use a similar dose of Chatel Guyon water, death is again bound to follow. On the other hand, this Chatel Guyon water neutralises the venom of the adder. And St. Nectaire water acts in a similar way against diphtheritic toxin. The toxin of tetanus is checked by La Bourboule water and not by Mont Dore, phallin poison by Mont Dore water and not by La Bourboule.

This is not true only for toxins treated in vitro; these various protective actions develop exactly in the same way if these various waters are injected hypodermically. But we must consider this extremely striking fact, that such protection, or *phylaxis* does not develop immediately, and only reaches its maximum after seven days. There is a period of incubation for phylaxis to develop, just as there is an incubation period for the toxin to develop its action.

As regards the protective action of certain mineral waters against certain microbes, there is no doubt experimentally that it does exist, but we are still in the early stages of elucidating the matter. How deeply do we feel the terrible loss Science has sustained from the premature death of Prof. Billard, the pioneer in this field of investigations!

We do not pretend that mineral waters have any sort of monopoly. They are an easy and cheap way of producing immunisation, but other electrolytes will certainly be discovered or invented which are endowed with the same property. Experiments made by that well-known biologist, Auguste Lumière, show that immunity—the production of antibodies—may be due to well-defined chemical bodies, such as saponin, a property that seemed to be exclusive to proteins. This goes so far that the serum of animals thus immunised acquires a protective action. We might call it chemical serotherapy. The protective action, this immunising action, by mineral waters is a new discovery, a most startling discovery, and one that is worth our active attention.

Mineral Water in Anaphylaxis.

Now I will ask you to consider, from a different point of view, the part which mineral waters play in the phenomena discovered by our great physiologist, Prof. Ch. Richet, which he calls anaphylaxis. Let us return to the solid ground of experimental facts.

If an animal be injected with horse serum and treated for 21 days with a daily injection of Vichy water, after which treatment a second dose of horse serum is given hypodermically, then the untreated control animals are found to die or become gravely ill, whilst the treated ones do not show the slightest reaction. This protective action is given also by Royat and La Bourboule waters. This is not merely the result of the action of water on a toxin. It is a true defensive reaction. It is due to the action of the bivalent bodies of the mineral water creating around the cells an electrostatic field of protection. We shall further consider presently this problem, which was studied and solved by Loeb, the American biologist. The phylactic action of mineral waters is far from being a general property. Prof. Perrin has experimented with the waters in the east of France. The results were positive with the Contrexéville and Vittel springs, negative with Luxeuil and Bourbonne. It is evident that the protecting property is not due to chemical composition. It does not develop if the waters are replaced by solutions of the same composition. Prof. Perrin suggests that it is the physical equilibrium that determines it, and most especially ionic dissociation.

We said a three-weeks treatment, and is it not a curious coincidence that the length of a "cure" in a spa has been fixed by clinical empiricism at exactly the same period?

Billard's Discovery.

The immunising property of mineral waters must certainly appear to you, as it does to me, as a most remarkable fact, and probably you are anxious to know how this discovery was made and why it should occur to any human brain to try such experiments. We might say hazard. Yes, but chiefly observation and open-mindedness, and perhaps a touch of genius. The story starts in so pretty a way that I fear I cannot resist the temptation of telling it.

Let us suppose ourselves transported to the centre of France, to the picturesque, volcanic district of the Auvergne mountains, a few years ago. It is a cold early spring morning, and the old shepherd has just given an outing to his flock after the long winter stabling under the snow. You may imagine the man, grey clad, standing like a statue on a black rock, leaning on his stick. The sheep are enjoying the fresh air, but there is very little to satisfy their appetite—just a few young green heads of broom, sprouting out where the snow has vanished.

Then watch a vigorous, middle-aged man climbing up the hill. He has escaped from his physiological laboratory in the medical school of Clermont Ferrand. It is Prof. Billard himself. He stops to talk to the peasant. The shepherd has two great opportunities of becoming an observer: time and silence. He listens to Nature. The scientist questions Nature. Well, it appears that at this time of the year the animals are depressed, and so clumsy that poachers have been known to outrun a wild goat. And, adds the shepherd, if bitten by a viper they suffer no ill-effects from the bite. A thought flashes through the mind of the scientist. To him the broom the sheep are feeding on implies spartein. These sheep are doped. And he knows that spartein is antagonistic to the toxin of tetanus. Why not to the snake venom, which has also a special affinity for the nerve centres? And down he walks towards his laboratory, determined to see the problem through.

Between spartein and the toxin there is a race for the nerve centres. If spartein reaches the goal first, it is too late for the toxin. Immunity is established. In order to diffuse spartein more rapidly through the organism, why not mix it with various electrolytic solutions? Billard has these solutions ready made at hand, and he tries the various mineral waters gushing up in his district. By chance he finds one neutralising the spartein he is experimenting with, and it is from this observation that he started his long series of researches, only stopped by premature death 12 months ago, from pneumococcal meningitis, within 24 hours of taking a winter stroll in his beloved Auvergne mountains.

Specificity and Sensibilisation.

We may here stop for a moment to consider by what means a certain mineral water may protect the organism against a specific toxin. A very similar point will arise when we have to consider the question of desensibilisation, and the part played by soaps. We may conceive that certain toxins, and for the sake of example we may select the tetanic toxin, have a special affinity, a positive chemiotaxy, for stearates. (And this may be inferred from the researches of H. Vincent.) Therefore, if a mineral water exists with electrolytes combined in such a way that with stearates it forms an insoluble soap, a barrier can be built, preventing the tetanic toxin from invading the neuron. The nervous tissues of those animals which are sensitive to adder venom fix the poison in vitro. But an emulsion of the neuron of the pig, an animal refractory to the venom, does not fix it. On the other hand, spartein is fixed by an emulsion of the neurons of all animals.

The question of time is of the utmost importance. Let us return to experimental findings. Tetanic toxin takes a certain time to develop its action, and the immunising action of the mineral water must be synchronised to the time of action taken by the toxin. For instance, we inject a dose of toxin lethal to the guinea-pig. One hour later we inject 10 c.cm. of La Bourboule water. The animal dies. The same result occurs if the water is injected three hours later. *The immunity has developed too soon. But if the* water is injected five hours later, the animal survives, because the immunising effect has occurred at the same time as the toxic action. If 12 hours elapse before the water is injected, then it is too late, and the toxin works before the immunising action develops; the animal dies.

Lipoids not Proteins.

If you want to understand such an action you must admit the working hypothesis of Billard, that we are sensibilised not by proteins but by lipoids. The fact is very likely, if we consider that coagulation by heat does not hinder in any way the anaphylactic effect of antigens. Why not admit, as a very likely possibility, that the lipoids are responsible? Billard himself has observed anaphylactic shock on guinea-pigs, prepared with lipoidic antigens from the calf and started with calf serum. Another instance of anaphylaxis by lipoids is the celebrated case described by the late Prof. Widal, of a sheep merchant who developed asthma from the mere smell of greasy wool.

If you admit such an hypothesis, then the part mineral waters play in the desensibilisation of the organism is made easier to understand, providing that in this instance again we consider saponification. Organic soaps mobilise not only lipoids but insoluble fats. It is an experimental fact that those mineral waters which dissolve soap most readily are exactly the waters endowed with the greatest power of desensibilisation against anaphylaxis. And if we examine such a mechanism from a different angle, we may admit that these waters introduce into the organism active electrolytes, which disperse the soaps and mobilise the lipoids more easily.

If such be the case, then we can foresee a new class of drugs, acting merely by virtue of their physical properties; in other words, by vibration. The production of such a material has been achieved by Roger in his laboratory of La Sorbonne in Paris, and the results appear quite satisfactory. It is used externally, in the same way as an embrocation. How it really acts is still a problem. Experiments are actually being carried out on plants at the moment. It seems that it is in this way that foreign lipoids are washed out of the organism and prevented from getting fixed. The combination during the period of incubation is checked, and when the "injection déchainante" is given there is no shock. We do not go so far as to pretend that proteins play no part in anaphylaxis, but we think they are controlled and determined by soaps and lipoids. It is through the latter that mineral waters play their protective part against anaphylaxis.

ORIGIN OF MINERAL WATERS.

That mineral waters prove to be very complex substances is no surprise when you think of their origin. I am speaking merely of the plutonic waters gushing up in volcanic districts. We know that they come from very deep, for, in the search for oil in the Auvergne, shafts have been bored over 3000 feet deep, and waters have been found quite similar to Vichy water, for instance. There is no doubt that they come from a far deeper layer still. They are not surface waters absorbed and rejected, but synthetic waters from distillation of granite at a very high temperature and under extreme pressure, under the action of carbonic gas. They come from what we might call the underground melting-pot. We know nothing of the condition of matter under these conditions, but we suspect it to be a sort of sample of the concentrated primary nebula. Mineral springs are the last remnants of plutonic phenomena; in fact, miniature volcanoes. The spectroscope reveals many constituents, and there is little doubt that still more will be revealed. Geologists have no explanation to give as regards the origin of the tremendous volume of carbonic gas produced during the succession of geological epochs. In a few words: mineral water is a very complex solution of electrolytes, which has not yet found, when it reaches the surface, its normal equilibrium.

If we consider the question from the historical point of view we see that there always has been some mystery surrounding springs. There were supposed to be a sort of emanation of the divinity, and some god or goddess presided over each. A spring was a shrine. Then came the empirical period. They did not speak of the *virtues* of waters but of their *action*. Some patients got cured, told their story, and sent to the same spring those who suffered from the same ailments. And that was the beginning of the specialisation of springs. Later on the waters were studied from the chemical point of view, and it is from the analysis of the waters that the scientist tried to deduce the explanation of their origin. It was not until the present century that their physical and biological properties were taken into consideration, firstly by a young French scientist, Fleig, who died quite young, leaving us a marvellous field of research and of investigation.

Their Biochemistry.

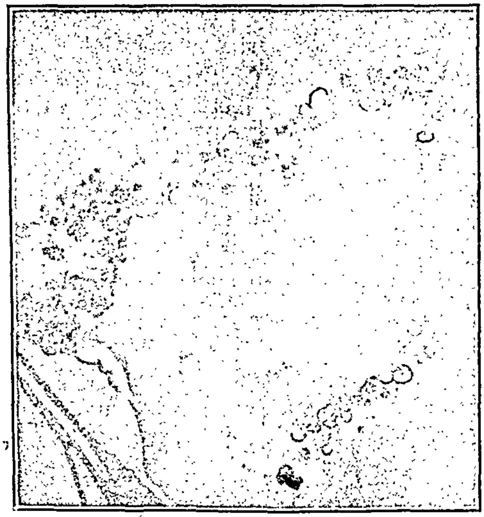
Let us now revert to the composition of mineral waters. We may take as a type the water that has been most especially studied: that of Vichy. Until lately chemists only told us about the elements which were present in large quantities, such as sodium bicarbonate and sodium sulphate. But lately Mr. Bardet, of the Institute of Hydrology in Paris, studying the composition of these waters with the spectroscope, has discovered a true secondary mineralisation, and has given us a new list of elements which were totally unsuspected. Of these we may mention lead, germanium, gallium, molybdene, copper, antimony, cobalt, mercury, nickel, gold, and thallium. As a matter of fact, this new list mentions no less than 42 elements, and there is very little doubt that when the list is completed it will include practically the whole list of the cosmic elements.

And now for the physicist. He in turn discovers quite a number of unknown properties: radioactivity, rare gases, phenomena of osmosis, of ionisation, of catalysis. He studies the colloidal equilibrium of salts, their electrical potential, and shows that they constitute a mechanical living complex, which cannot be compared with any artificial solution and which would baffle the efforts of synthesis.

Some day much more will be known about these actual problems. We may prophesy safely that the physician of to-morrow will have to be a biochemist. He will know about health and disease vibrations. He will know how to measure them and how to use them. A good deal has been done already, but the work of the pioneers has not yet reached the scientific stage when results can be given in figures by mechanical means. An example of such a device is given by Prof. Puech, when he measures the electrical exchanges between a patient in a bath and the water of the bath. He has shown that certain organisms work like a battery, taking on or letting off electric charges. This should be a guide to us in physical treatment. On the other hand, we have all heard of methods aiming at the detection of life emanations and at measuring them; but such methods failed to exclude in their measurements that personal equation which does not allow control. Yet it might happen any-

It seems to me most probable that diverticula start as true pulsion herniæ of the mucous membrane through the ridges in the circular muscle coat at the weak points where the blood-vessels enter, and that after their formation a retained fæcal content is likely to set up inflammation which spreads to the neighbouring tissues. This secondary inflammation may never occur, or it may take place at almost any stage in the development of the pouches. The nature of the process which starts the condition is at present only conjecturable, but it seems probable that some degeneration of the bowel wall, probably from age and unnatural conditions of the bowel function, is the initial factor. In favour of this view is the fact that the condition is practically confined to the second half of life and that diverticula of the colon are most frequently seen in fat persons. I have seldom seen a thin individual with diverticulitis. The rapid deposit of fat is generally a sign of poor metabolism and is usually accompanied by a marked degeneration of the musculature. It is probably this degeneration of the muscular wall of the bowel which explains the common association of excessive fat and the development of diverticula in the colon.

FIG. 4.



Radiogram of barium enema showing diverticula all along the colon, taken after evacuation of the barium from the bowel.

I have been fortunate in obtaining a specimen (Fig. 3), which shows the development of inflammation in the colon wall as a secondary result of a diverticulum at a very early stage. It will be seen that the diverticulum has pushed its way right through the muscle coat into the subperitoneal tissue and that an abscess has begun to form round its tip, probably as the result of the small foreign body present in the apex of the diverticulum. This specimen shows the very earliest stage in the development of a diverticulitis, and it is easy to realise that if this condition occurs over a large area of the colon wall it will in time produce the typical fibrous stricture that we see in cases of this type of diverticulitis.

Two Varieties of Diverticulitis.

There appear to be two very different and distinct types of case commonly seen. In the first the colon wall becomes inflamed over a fairly wide area at a very early stage in the development of the diverticula, as seen in Fig. 3. This results, in course of time, in very dense and progressive thickening and fibrosis of the colon wall in the affected area. Ultimately a firm fibrous stricture develops, with greatly thickened walls and firm adhesions to surrounding structures. This type of case from a clinical point of view closely resembles carcinoma of the colon, and is not infrequently mistaken for it. X ray photographs fail to show the condition well, as the narrowed pouches do not readily fill with barium solution. This type of case can only be treated satisfactorily by resection of the damaged area of colon, or by establishing a colostomy opening above the obstruction.

The second type is the commoner and is that in which the diverticula develop and grow, often to a considerable size, without any accompanying inflammation. Such cases are rightly called diverticulosis to distinguish them from the inflammatory type (see Fig. 4). No symptoms are present and the disorder is only potentially serious. Inflammation may eventually occur, as the result of the irritation set up by hard retained fæcal matter in one or more of the pouches, with the result that an abscess forms outside the colon or there is perforation into the general peritoneal cavity with peritonitis. Obstruction may result from adhesions, but is not so common as in the first type, and the same dense thickening and fibrosis does not occur.

Conclusions.

1. The earliest stage in the development of diverticulitis is the formation of pulsion diverticula in the colon wall due to weakness of the musculature. 2. Inflammation is always secondary and is due to foreign bodies or fæcal material getting into the diverticula. 3. The X ray appearances which have been supposed to be due to inflammation are due to very small but numerous diverticula of the mucous membrane. 4. Secondary inflammation of the pouches may occur at an early stage and produce dense fibrosis; it may not occur at all, or only very late in the development of the diverticula.

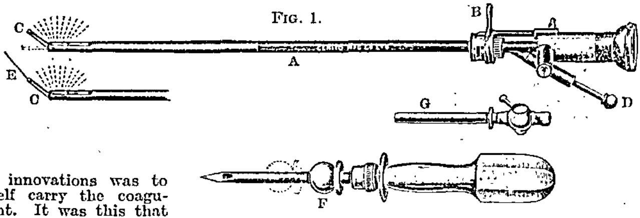
A NEW THORACOSCOPE.

BY F. G. CHANDLER, M.D. CAMB.,
F.R.C.P. LOND.,
PHYSICIAN WITH CHARGE OF OUT-PATIENTS, CHARING CROSS HOSPITAL; PHYSICIAN, CITY OF LONDON CHEST HOSPITAL, VICTORIA PARK.

THE instrument to be described embraces new principles in thoracoscope construction. The one instrument serves the double purpose of endoscope and active electrode for cauterising; thus only one puncture is needed. It is used with a diathermy current. It is made by Mr. R. Schranz, of the Genito-Urinary Company, who has given up a great deal of time in coming to the City of London Chest Hospital to study at first hand the problems involved. We believe that we have evolved an instrument which is in certain respects an advance on previous ones, the handling of which is easy, and which very greatly facilitates the technique of severing adhesions. The original Jacobæus instrument I personally found difficult, and, judging by the number of its modifications, others have evidently had the same experience. The field of vision, at right angles to the instrument, was awkward. Moreover, two punctures were necessary. Cauterising might be long and tedious; and smoke would not infrequently obscure the view. On reading of the Davidson operating thoracoscope (New York), I tried this, and after a considerable modification of the electrode by Mr. Schranz, I found it very good; it is this instrument that inspired the work on the one to be described. There are, however, in my opinion, two or three rather strong objections to the Davidson instrument. Firstly, it is too big. The wound made is unpleasantly large. Secondly, it is oval in shape, which increases the chances of surgical emphysema as the instrument has to be rotated during use, and so opens up the tissues to the pneumothorax. Thirdly, the instrument itself has to be pushed to and fro in the chest wall during manipulation, instead of working in a cannula like the Jacobæus instrument, this again making surgical emphysema and sepsis more likely, and leaving a wide opening into the pleural cavity which needs very careful stitching afterwards.

The advantages of the new instrument may be summarised briefly as follows: 1. Its small calibre (18 Charrière gauge). 2. Its working through a cannula. 3. The need for only one puncture. 4. The excellent field of vision, which is at an angle of only 30° off the axis, thus simplifying orientation. 5. The electrode being placed just beyond the lamp it is as easy to touch as to see an adhesion. 6. It is a diathermy instrument—the current being absolutely under control of the operator by a foot-switch. With this current a suitable adhesion can be first coagulated and then cut through in a few moments, with no production of smoke. 7. The whole instrument can be boiled.

FIG. 1.



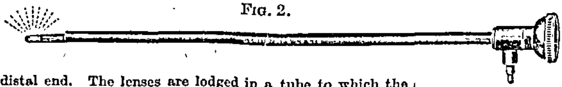
One of the principal innovations was to make the telescope itself carry the coagulating and cutting current. It was this that enabled the size of the instrument to be made reasonably small. The coagulating electrode is large, thus rendering dangerous hæmorrhage practically an impossibility. Through this large electrode is pushed, by a simple device, the cutting wire made of tungsten, which is strong and not easily bent.

Description of the Thoracoscope.

The following is a more technical description of the instrument (Fig. 1).

It consists of a metal sheath (A), 25 cm. long, covered with a special insulating compound on the outside. The distal end has a terminal and a lateral opening. At the junction of these a round bar is fixed, which acts at a pivot for the diathermy electrode. At the proximal end a revolving collar with a helical groove controls the movement and position of the telescope (B). By means of this device the movement of the telescope along the axis of the sheath imparts the requisite tilt to the hinged electrode at the distal end. The lenses are lodged in a tube to which the lamp is attached; at the junction of the lamp a prism deflects the optical axis by 30°. The lamp case carries the actual diathermy electrode which is hinged to the case (C). A fine tube runs along the telescope from the proximal end to the junction of the lamp; it then continues at the bottom of the lamp case, and emerges at the joint of the diathermy electrode with the lamp. Through this fine channel a tungsten wire passes right to the tip of the hollow diathermy electrode. The wire is controlled at the proximal end by an insulated handle (D) by means of which it can be pushed forward, beyond the diathermy electrode, to the extent of three-quarters of an inch (E), and withdrawn at will.

FIG. 2.



The cannula of the trocar with which the chest is punctured, and through which the instrument is passed, has an adjustable guard in the shape of a ball (F); this can be clamped at any distance from the end of the cannula. If, for any reason, the thoracoscope has to be temporarily withdrawn from the pleural cavity, a faucet (O) with tap is inserted into the opening of the cannula to prevent escape of air. This also allows fluid to be withdrawn or air to be introduced if needed, pressures to be taken, &c.

This instrument suffices to deal with suitable adhesions favourably located. If, however, the lung is attached to the parietal pleura by a short adhesion, or one into which lung tissue projects, great care must be exercised to sever such a structure close to the parietal pleura. For this local or general anæsthesia is probably necessary, preferably the former. For this purpose we have devised an instrument very similar in construction to the cutting thoracoscope. In this the diathermy electrode and the wire channel are replaced by a fine cannula with a hypodermic needle at the tip. Another possible use suggested for this instrument is the injection of an adhesion with lipiodol, when very considerable doubt exists of the presence of lung tissue; subsequent radiography will give the desired information. Experiments I have made with meat similarly injected suggest that if the injected adhesion is afterwards severed by diathermy no free iodine is liberated.

In addition to the instruments already described, two additional wide-angled telescopes for a preliminary examination of the pleural cavity can be used, one having the optical axis deflected at the same angle as the operating instrument (Fig. 2), the other at an angle of 90°, which would enable one to view a side of a wide adhesion inaccessible to the other telescope.

When an adhesion is located, a portion about 8 mm. long is coagulated, the diathermy electrode being applied both to the back and the front of it, if necessary. The tungsten wire is then pushed forward and applied to the centre of the coagulated section. The cutting current is now switched on, and the adhesion severed. Purely fibrous bands can be cut through in a second without previous coagulation, as there is no bleeding. A special diathermy apparatus is used for this purpose, designed by the Genito-Urinary Company, producing a coagulating (diathermy) and a cutting (endothermy) current. A selector switch is fitted on the top of the panel by means of which either one or the other type of current can be applied. The apparatus is controlled by the operator himself by a foot-switch. The strength of the current is regulated according to the size or resistance of the adhesion, and for this purpose a regulator with an empirical scale marked 0–10 is provided. The patient is connected to the other pole of the machine through an indifferent electrode—that is, a large-sized lead plate covered with a towel soaked in 10 per cent. saline solution. This is placed on the operating table and the patient lies on it, thus making good contact with his own weight.

NORTH STAFFORDSHIRE CRIPPLES' AID SOCIETY.—This society proposes to enlarge the Cripples Hospital at Hartshill, Stoke-on-Trent, at a cost of £20,000, and it is stated that the Ministry of Health regard the plans as "a model for similar institutions." The enlargements will include a new out-patient department, an operating theatre, an X ray room, and accommodation for nurses and staff. Viscountess Ednam, president of the society, points out that much of the work of an orthopædic hospital can be carried on by means of out-patient treatment, which at Hartshill, costs approximately 7*s.* per week, as compared with £2 0*s.* for in-patients.

in isolation, and further one would expect that infection in man with such an organism would result in unequivocal serological eivdence of its presence; this, however, has not been forthcoming.

We have had the opportunity to investigate 12 human cases diagnosed as psittacosis and six parrots connected with these cases; one of the human cases came to autopsy. In none of these have we been able to obtain any evidence. either bacteriological or serological, of the presence of any member of the salmonella group.

In view of our negative findings and of those contained in the literature we decided to approach the problem from a different angle. It occurred to us as possible that this disease in parrots is caused by a filtrable virus which may under favourable conditions be capable of infecting man. Using the budgerigar as our experimental animal we have been able to demonstrate the presence of a filtrable virus in the organs of a parrot which had been responsible for two human cases. The bird was ill when it reached us, and died in the course of a day or two; bacteriological examination of its tissues gave entirely negative results. Although no quantitative experiments have been carried out our findings suggest that the virus passes readily through Chamberland L1* filter candles and passage in budgerigars with filtered material has been realised. The parrot tissues are still virulent after being kept for 20 days in 50 per cent. glycerol saline in the cold.

Further experiments are being carried out along similar lines with material from other diseased parrots and also from human cases. We are not in a position to say that this virus is the cause of the disease in man, but we consider that our findings suggest that possibility. We are fully aware that the parrot is susceptible to the virus of fowl plague and that we may be dealing with this virus. Experiments designed to determine this point are being carried out.

In conclusion, we wish to express our thanks to our colleagues of the London Hospital, to the Ministry of Health, and to doctors who have kindly put us in touch with material.

HYPERVITAMINOSIS D:

CALCIUM-PHOSPHORUS INTAKE A DETERMINING FACTOR.

By Leslie J. Harris, Sc.D., Ph.D.,

DIRECTOR OF THE MEDICAL RESEARCH COUNCIL'S NUTRITIONAL LABORATORY, CAMBRIDGE.

I am prompted to write the present brief summary of observations to be published in detail later by the consideration that they may suffice to account for the failure of certain workers to reproduce consistently results which have been more readily confirmed by so many others.

Harris and Stewart[1] in 1929 found that administration of excessive vitamin D to rats and rabbits tended to give rise to hyperphosphatæmia and/or hypercalcæmia, a result since confirmed in more extended series of experiments. Since this, as well as the other effects observed, were the opposite of those seen in vitamin D deficiency we concluded: "There are low and high threshold values for vitamin D below and above which there are caused deficient and excessive values respectively of blood-phosphorus and/or blood-calcium and resulting calcification" (Harris and Moore).[2] Now in rickets the primary disturbance is apparently a lowered retention of phosphate or calcium from the gut, with consequent lowering of blood P or Ca, and a resulting deficient "calcification"; and the severity of the condition is largely dependent upon the absolute and relative amounts of these two elements provided in the diet. It was therefore suggested (Harris and Stewart)[1] that the same considerations might also be of consequence in hypervitaminosis D. My present purpose is to mention findings which confirm this idea.

In the first experiment to be described I have fed rats on "synthetic" diets containing a constant known excess of irradiated ergosterol with various graded allowances of calcium phosphate. The results show that the ill-effects produced by the excessive vitamin D (as judged by growth responses, by condition of animals, by extent of calcification and other post-mortem findings, and by histological examinations by my colleague Mr. J. R. M. Innes) are immensely accentuated by any increase of the calcium phosphate and conversely are prevented by a decrease. In another experiment it was found that rats fed on bread and milk in place of the usual "synthetic" rations developed typical hypervitaminosis provided they were given sufficient irradiated ergosterol (0·1 to 0·2 per cent.) and for a sufficient period (e.g., within 45 days). Further, by adding the usual percentage of synthetic salt mixture (rich in Ca and P) to the bread and milk employed as basal diet, these symptoms were greatly accelerated and intensified. (This last experimental result may perhaps explain the recent observation of Prof. Dixon[3] who wrote, "The same experiments made on animals living on an ordinary diet show that the excess of the 'poisonous' food is harmless. For example, certain preparations of irradiated ergosterol given to rats which are being fed on a synthetic diet act as a poison, *but if the rats are fed on bread and milk the effect of the ergosterol is negligible.* In real life we do not live on a completely synthetic diet; nearly everyone takes some if not an abundance of fresh food, so the practical value of this type of experiment may be over-estimated, though it is of considerable academical interest.")

A further point of interest is the possible effect upon the calcium (or phosphorus) retention of changes in the Ca : P ratio of the diet. We found, for example, in experiments concluded about a year ago that rats fed on the high Ca : low P "rachitogenic" diets of Steenbock or of Pappenheim rapidly developed a fatal hypervitaminosis when excessive vitamin D was added.

It is seen, in short, that the occurrence or severity of the hypervitaminosis is determined not only by the degree of vitamin D excess administered and the length of the experimental period but also by the calcium and/or phosphate content of the diet. This observation no doubt accounts for a certain amount of confusion which is evident in the literature; it is of further interest in throwing light on the mode of action of vitamin D in the animal body. It might be added that a fair number of clinical cases of hypervitaminosis (resulting from injudicious use of therapeutic preparations) have now been reported by physicians in Europe and in America, in which the main symptoms are the same as those seen in the experimental condition—viz., high blood P and Ca and excessive calcification. Bearing, too, on these findings is the observation of Miss Elsie Watchorn (in the press) that the hypervitaminosis gives rise to a greatly increased excretion of Ca by the kidney. Direct measurements of Ca and P retention are now in progress. Contrary to the suggestion of A. F. Hess (1928) we find by chemical analysis that there is no loss of Ca or P from the bones to account for the rise in the blood figure.

Accidents at Sheffield.—During 1929 the number of traffic accidents dealt with by the Sheffield Royal Hospital was 1152; 358 of the cases were admitted to the wards. The total number of casualties treated during the last three months of the year was 5624, as compared with 4601 in the corresponding quarter of 1928. Of the traffic casualties 75 per cent. were caused by motor-cars and motor-cycles. The 358 patients admitted to the wards spent 6710 days in hospital at an average cost per head of £6 17*s.* 5·39*d.* Of the total costs of £2460, £2199 was recovered.

Medical Societies.

ROYAL SOCIETY OF MEDICINE.

SECTION OF MEDICINE.

AT a meeting of this Section on Jan. 28th, with Dr. R. A. YOUNG, the President, in the chair, a paper on

PSITTACOSIS

was read by Dr. A. P. THOMSON (Birmingham). With the four cases described in a previous communication,[1] he said, the total number he had now seen was 17, of which 5 had proved fatal. As a general statement it was fairly accurate to say of the severer cases that they resembled typhoid septicæmia in retaining a relatively slow pulse despite a high continuous fever. Even before the development of the unusual pulmonary signs, however, certain features distinguished them from true typhoid: the onset was usually more sudden and the temperature rose more rapidly. Headache was intense, generally occipital in situation, and often associated with slight cervical rigidity. Epistaxis had been noted in one patient. Sweating was sometimes severe. Diarrhœa and vomiting sometimes occurred in the early stages, but as a whole, the alimentary symptoms, apart from distension, were trivial. The spleen became palpable in one case and then only for a few hours; no rose spots had been observed. In one case there had been a typhoid-like relapse. The outstanding feature of the clinical picture was the involvement of the lungs. At the onset signs of slight shifting bronchitis appeared, to be followed in a few days by those of extensive consolidation manifested by impairment of the percussion note and the presence of tubular breath sounds. Still later the percussion note became completely flat and breath sounds in the affected area disappeared. This curious silence of the lung might persist for some days after the temperature had fallen and the general condition had improved. A whole lung might be affected in this way. Resolution was very rapid and complete, and was accompanied by fine crepitant râles. Repeated exploration of the chest having shown that these signs were in no way due to pleural effusion, Dr. Thomson concluded that they were associated with obstruction of the smaller bronchi. Confirmation of this opinion was afforded by a post-mortem examination in one of the cases.

Certain negative features in the respiratory condition were important. Although cough was frequent and at times incessant it was never painful, and expectoration was scanty and often absent; only once was any rusty sputum obtained. Respiration was not hurried unless the area of lung involved was very extensive; it was easy and never "pneumonic" in character. Pleuritic friction was never found. Some of the patients had conspicuous nervous signs. Although the clinical course of most of the cases formed a fairly characteristic picture it was clear from a review of the whole of them that the symptoms and signs might be but slight and equivocal—even when the disease proved fatal—and a diagnosis would be frankly impossible unless the history of contact with sick birds was elicited.

Bacteriological Aspect.

The bacteriological findings, said Dr. Thomson, were as yet incomplete, and it would be unprofitable to review them at length. In the earlier part of the investigations a review of such literature as was available had led him and his colleagues to concentrate attention on the discovery of an organism of the typhoid or salmonella type. In the first case a bacillus corresponding fairly well with this group was recovered from a local parotid swelling but in none of the subsequent cases had there been any success so far. A remarkable feature was the recovery of an organism similar in its sugar reactions to *Bacillus fæcalis alkaligenes* from the lung in three cases, and also from the love-bird responsible for the infection of two other cases. Whether or not this organism was responsible in any way for human infection was a problem still under investigation. The results of the agglutination tests were extremely irregular and capricious. In two cases positive agglutination to a typhoid organism were obtained but in nine others there was none. Not much reliance could be placed on positive agglutination with *B. psittacosis* or the salmonella group generally as a means of exact diagnosis, particularly when, as in this series, they were often so transient and variable.

Discussion.

Dr. ROBERT HUTCHISON said he was genuinely grateful to Dr. Thomson for his patient work on this subject, for had it not been for that he would not have recognised the nature of the first case of the kind which came to him in London, since which date he had had considerable experience of the disease. The paper he referred to was Dr. Thomson's contribution to a meeting of the Association of Physicians last spring. Since then he, the speaker, had been in touch with over 20 cases of the kind; four were at present in London Hospital. In the 22 cases there had been, so far, two deaths. The instances of the disease had been enthusiastically investigated by Dr. Levy Simpson at London Hospital. The cases had mostly occurred in house outbreaks—i.e., two to four cases occurring in one family; there had always been a parrot, usually the Amazon green variety. He did not agree with the statement that psittacosis was only found in green parrots; in this series one was a grey parrot. In most of the 22 cases the infection appeared to have been directly from bird to human patient; in one case the patient had not been in close contact with the parrot in question, but she had been in close communication with a sister who had, and had used the same handkerchief. She was now recovering in London Hospital. Apparently the incubation period was about ten days. It was the same condition as occurred in France, where it received the not inappropriate name "pneumotyphus." When patients were seen the condition looked as if it ought to be typhoid or paratyphoid. In none of his cases was there found the hard dense consolidation of the lung which Dr. Thomson described. In most of the speaker's cases there was an impaired note and medium moist sounds. One patient—who died—had pleurisy, and at the autopsy a condition of pneumonia was described as present. Prof. Turnbull said it was unlike any ordinary pneumonia, either croupous or bronchial. Dr. Hutchison agreed with Dr. Thomson that the diagnosis of psittacosis must always be circumstantial at the moment—the fact of the disease occurring in a house which harboured a sick parrot. At present the bacteriology was vague and indeterminate. There was a good deal of psittacosis at present in London; in response to a letter from himself in the medical journals he was told of four additional cases, and probably cases were being overlooked. Last July a bad outbreak of the disease took place in the Argentine Republic, whence many of the birds had been brought to Europe, but a knowledge that such an epidemic occurred had only slowly filtered across the Atlantic. No cure had been found for the fully developed disease. In Germany the importation of parrots had been forbidden; England was attempting to protect herself by imposing quarantine on these birds. To be effective it seemed that this period of quarantine must be a prolonged one. Perhaps the Ministry of Health would investigate the matter.

Dr. E. STOLKIND spoke of two patients under his care whose symptoms pointed to psittacosis, though both made a complete recovery. He found in one case that the parrot being kept in the room was obviously ill, and he ordered its removal, but this was method) the use of platinum needles with an over-all length of 22·5 mm., each containing 5 mg. of radium, buried them at such distances apart as, it was hoped, would produce homogeneous irradiation of the growth. At first the radium was left in place for 24 hours, and then subsequently for 36 hours, at a time, because the resistance of the malignant cell to irradiation increased if its nucleus was not destroyed at the beginning of the treatment. The complications in this method were difficulty in micturition, caused by œdema of the urethral mucous membrane, sloughing—the result of over-dosage—and stricture of the external meatus. Opinions differed about the treatment of inguinal lymphatic glands; he himself did not operate upon these nor irradiate them unless the skin over them had ulcerated, for if the squamous cells of a penile cancer had entered the inguinal glands they would not go any further, while if the primary growth had been irradiated, these cells would not multiply, but would be ringed round by a defensive fibrosis. By irradiation the penis was preserved, and though stricture of the external meatus might sometimes result, its frequency was not comparable to that observed after amputation.

---

[1] THE LANCET, 1929, ii., 115.

Mr. Morson's conclusions were briefly as follows. In both papillomatous and ulcerative varieties of penile cancer the growth could be made to disappear, but there was no guarantee of cure. The moral effect of removing the tumour while retaining the penis rendered irradiation the method of choice. Recurrence could be met by further irradiation and health could be so much improved that the patient could stand a Pearce-Gould operation if necessary. If most of the penis had already been destroyed, total amputation was the correct treatment.

Discussion.

The **President** said he had not treated carcinoma of the penis with radium, but he agreed that the psychological effect of retaining the penis was important. He hoped Mr. Morson's statement that epithelial carcinoma was stopped by the glands was true.

Mr. **F. Fowler Ward** (Ipswich) said that on looking up his cases of cancer of the penis in the last ten years he found in none of them had the growth recurred. One patient had died of what appeared to be a secondary effect in the lung. The only immediate fatality he had had was one in which the femoral vein was torn, death following from hæmorrhage in 30 minutes. He was much impressed by what Mr. Morson had said about the use of radium in these cases.

Mr. **Eric Pearce-Gould** considered that in the future there would be no need to inflict on patients the full horrors of the radical operation. His last case was treated with radium, and the result was very satisfactory.

Mr. **Frank Kidd** discouraged belief in a cure of these cases by radium. In performing the Pearce-Gould operation he had never had difficulty with sepsis, nor was there stricture of the urethra. He was not aware of his patients having had inferiority complexes; they seemed happy and comfortable. A much longer period should elapse than Mr. Morson had mentioned before speaking of cures by radium.

Mr. **R. H. Jocelyn Swan** did not think Mr. Morson claimed to have brought about cures, but he indicated the progress which had been made in treatment. He objected to Mr. Morson's statement that the cells having got to the inguinal glands they went no further; he could produce evidence to the contrary. He would prefer to use a small dose of radium over a longer period than a larger dose for a short time, and he would concentrate the irradiation as a barrage at the growing edge. The epithelial type of new growth was well fitted for treatment by radium.

Mr. **H. W. S. Wright** spoke of the prevalence of penile cancer and warts and phimosis in China. Most of the cases of cancer of the penis which he saw there were of the cauliflower type. He treated them by an operation approximating to that of Pearce-Gould. He had only one death, and that was due to septicæmia.

Mr. **Morson**, in his reply, said he had seen a considerable number of cases of carcinoma of the penis in which the primary lesion was in the prostate, and in most of the cases where metastases were found, other than in the inguinal glands, the primary lesion was in the prostate, not in the penis.

MEDICAL SOCIETY OF LONDON.

At a meeting of this Society on Jan. 27th, with Mr. **Donald Armour**, the President, in the chair, a paper on the

Ætiology of Gall-bladder Infections

was read by Prof. D. P. D. **Wilkie** (Edinburgh). To some it might seem presumptuous, he said, for a surgeon to enter on discussion of this subject, but present-day knowledge of the gall-bladder was largely due to the observations of surgeons. So commonly was this organ diseased, and so often were stones present in it, that the pathologist was apt to discount its importance, while post-mortem changes took place in it so rapidly that early lesions might readily be missed. Numbers of patients were operated upon because they had had a chronic flatulent dyspepsia associated with some ill-health—apart altogether from biliary colic—and in many of these cases, although there were no stones in the gall-bladder, there was a definite change in its wall. Cholecystectomy had been found to give relief, not only to the flatulent dyspepsia, but also to other symptoms, and gradually the idea had been evolved that the gall-bladder might not only be the seat of inflammation, causing local symptoms, and of stone formation, causing colic, but that it might also be a focus of infection affecting other parts of the body.

The gall-bladder was a concentrating organ; it concentrated bile ten times in the course of 24 hours, both the pigment and the salts. And the important question arose whether it possessed the power of spontaneous contraction, and whether it could empty itself by means of its own musculature. Prof. Wilkie thought it could. Ivy, of Chicago, had shown that from the upper part of the small intestine one could isolate a gall-bladder hormone, a purified secretin, which, when injected intravenously into animals, caused the gall-bladder to contract.

Cholecystitis and Gall-stones.

What was the origin of cholecystitis? Did it always precede gall-stones, or did gall-stones precede it? There was a good deal of evidence that certain types of stone might form independently of any infection, and particularly the pure radiate cholesterol stone, which was usually single, ovoid, opalescent, and was found in a gall-bladder which was not thickened and was unassociated with a history of previous febrile attacks. Sometimes this received the name of "metabolic" stone, as it was supposed to be laid down because there was an excess of cholesterol in the bile and some stasis in the gall-bladder. It produced an afebrile colic which was intermittent, and inaugural symptoms due to cholecystitis were absent. At any time such a stone might be impacted in the neck of the gall-bladder and cause an attack of biliary colic. In such an event the gall-bladder filled with mucus. The stone might remain impacted and leave the patient with a mucocele of the gall-bladder, or it might fall back again as the tension diminished. The pure pigment stone was not often seen, but was typically associated with acholuric jaundice; it was not associated with cholecystitis, even at a later stage. The septic, faceted stone, which had a cholesterol centre and laminæ of cholesterol and calcium, might appear secondarily to a primary stone, or might form independently.

Primary infection of the gall-bladder, went on Prof. Wilkie, was undoubtedly very common; Graham, of St. Louis, thought that 35 per cent. of the adult population had some degree of infection of the organ.

The route by which bacteria reached the gall-bladder had been much in dispute. Many were taught that infection travelled from the duodenum, up the bile-duct, and so to the gall-bladder, duodenal catarrh being a predisposing factor. Some thought it came down from the liver in the bile stream, but most of the evidence was against this suggestion; if 40 c.cm. of an emulsion of *Bacillus coli* was injected into the portal vein of an animal, it could not be recovered from the gall-bladder on the following day. It was, as a matter of fact, difficult to infect, from the lumen, any hollow viscus which had undamaged mucous lining. Graham brought forward strong reasons for thinking that infection travelled from the liver to the gall-bladder, and that hepatitis preceded the cholecystitis, but there was now evidence that this was not the usual route of infection. At one time it was thought that typhoid infection was the most potent cause of cholecystitis, and it was true that typhoid did infect the gall-bladder, and that a patient might have a chronic typhoid cholecystitis for many years. That was not the common type, however, in Prof. Wilkie's opinion. In his own series of 650 cases—almost all of which had been examined bacteriologically—there had not been a single one of typhoid infection. Both colon and typhoid bacilli could flourish in bile, and from many infected gall-bladders the former could be recovered. What struck him and his colleagues most in examining gall-bladders was the number of cases in which there was neither a growth of organisms in culture nor the ability to demonstrate them in microscopical sections. Extending the series, a number of cases were found in which chains of micro-organisms were demonstrated, though culture from the gall-bladder wall was sterile. The work had been continued during the last 3½ years, and the results had been fairly consistent; they had been able to grow a streptococcus from 32 per cent. of the cases, and *B. coli* in 14 per cent. It was safe to say that just over half these gall-bladders gave a positive growth of streptococcus. Success in this work began when only a small piece was taken for culture, avoiding the mucous membrane, and particularly when the cystic lymph gland was used. Even then, however, the result was negative, unless the gland was removed at the end of 4 to 6 hours. For the organism would not grow if there were autolytic products, or if there was much bile in the medium.

Prof. Wilkie showed the following Table which showed, he said, remarkable difference in the incidence of hospital and private cases.

Gall-bladder Cases, 1919–29.

—	M.	Av. age.	F.	Av. age.	Total.	Av. age.
Hospital ..	61	48	298	46	359	46·5
Private ..	92	56	207	51	299	53
Total ..	153	—	505	—	658	—

M = male; F = female; av. = average.

Operations.

—	Ch.	Died.	St.	Died.	Per cent. mortality.	
Hospital ..	266	6	59	1	2·1	2·73 av.
Private ..	186	6	86	5	4·04	

Ch. = cholecystectomy. St. = cholecystostomy.

Medical and Surgical Treatment.

The investigation, he said, had altered his conception of cholecystitis, for he believed it was, in the majority of cases, a blood-borne intramural infection of the gall-bladder, and therefore difficult to eradicate. The only medical means of doing so seemed to be to raise the general resistance of the patient to the organism, or if possible, to give some drug which was absorbed by the gall-bladder; the surgical alternative was to remove the infected organ in which streptococci had become located. This knowledge meant that the operation of choice was not drainage of the gall-bladder, but removal of its infected wall. A criticism sometimes heard was that people were not well after their gall-bladder had been removed, and he knew of several people who complained of symptoms after cholecystectomy. But where such cases had been investigated properly, and especially if they had been operated upon again, some cause had been found for the residual symptoms: a stone previously unnoticed had been left behind, or there was pancreatitis, or a coincident ulcer had been missed, or appendicitis, or even unrecognised malignant disease in the colon. Could one hope, by ordinary drugs, to affect beneficially a lesion which was intramural? Prof. Wilkie still was doubtful about that. When secondary infection of the colon was present considerable benefit could be got by medical biliary drainage or by giving certain drugs, such as urotropine; but for the chronic indolent type of streptococcal intramural infection very little could reasonably be expected from drugs, and if the condition was persistent and disabling, operation was the only rational treatment.

Discussion.

IN seconding a vote of thanks proposed by Mr. V. WARREN LOW, Mr. HERBERT CARSON remarked that this recent work left no alternative to the conclusion that at present the right treatment of chronic cholecystitis was surgical.

Mr. A. J. WALTON said his own experience of this subject had been mainly clinical, but it largely accorded with what Prof. Wilkie had established from the pathological side. He thought the cholesterol gall-stone was always due to inflammatory change. He had found that the pure cholesterol stone was always single and relatively small and amorphous in its outer layers. If Aschoff had been correct, cholesterol stones would have been found as a crystalline formation. He agreed with Bland-Sutton that crystallisation was always a secondary change. He, the speaker, had had 23 cases in which there were pure cholesterol stones; 5 of them had acute, and 18 chronic, cholecystitis. He had not seen such a stone in any case in which there was no evidence of cholecystitis. In his opinion Prof. Wilkie was right in thinking that gall-bladder infection was always blood borne. The gall-bladder lesion was the residue of a mild septicæmia. Many cases came with inaugural symptoms which were those of a general infection; they came to hospital with what was called influenza or pyrexial conditions, with pain. They were treated, but began to develop dyspeptic symptoms, and later they had tenderness over the gall-bladder passing on, perhaps, to cholecystitis. If left alone, the case became one of gall-bladder trouble.

Dr. J. W. MCNEE said his work made him believe that cholesterol stones occurred in gall-bladders which were not infected, and whose walls were not infected. Recently he had had the opportunity of testing Prof. Wilkie's conclusions on the bacteriology of the gall-bladder, and in most of the cases he had examined the gall-bladder contents were sterile. He had not, however, been able to examine the bacteriology of the gall-bladder wall, like Prof. Wilkie. What could be done from the medical standpoint to prevent to some extent the formation of gall-stones in cases of chronic cholecystitis was to use simple duodenal drainage, or to give concentrated magnesium carbonate by mouth in the early morning so as almost to empty the gall-bladder. The normal means of emptying the gall-bladder was the introduction of fat through the pylorus into the duodenum. Though he had seen many operations in this region, he had never seen a gall-bladder completely empty. He was sure that there were a fair number of cases of chronic typhoid and paratyphoid infection of the gall-bladder going about. A pure culture of typhoid bacilli might be obtained at operation twenty years after the initial infection. From the point of view of the physician, if the commonest variety of chronic cholecystitis was due to an intramural infection, he did not see how it could be expected to be curable by medical means, except by increasing the patient's resistance. But much could be done in preventing gall-stones, either by biliary drainage—which was more simple than many imagined—or by the use of such a tube as he passed round for inspection.

Dr. H. W. Crowe said he was glad to hear that Prof. Wilkie and his collaborators had succeeded in growing streptococci from the wall of the gall-bladder in these cases, also from the cystic duct; he had often tried himself, but without success. A woman patient of his with rheumatoid arthritis developed a very acute gall-stone colic, and when he examined her fæces after giving magnesium sulphate he found an almost pure culture of streptococcus. It was the kind which almost always caused rheumatoid arthritis in the rabbit, and it attacked the marrow of the bones more than the articular ends.

Prof. Wilkie, in reply, said he was inclined to agree with Mr. Walton that the cholecystitis was a residuum of a general infection, what could be called a septicæmia. The only occasion on which he had seen a completely empty gall-bladder was in a patient who had a tumour at the junction of the two hepatic ducts. In five cases he had found *B. welchii;* three were acute cholecystitis cases of the gangrenous type, and they had the marked pallor seen during the war in patients suffering from gas gangrene. He had not found arthritis in the rabbits studied in the series. A careful study of tonsils revealed a large number harbouring *Streptococcus viridans*, and when this was injected into rabbits it caused definite cholecystitis in three.

LONDON CLINICAL SOCIETY.

At a meeting of this Society held at the London Temperance Hospital on Jan. 28th the chair was taken by Mr. Herbert Paterson, and Dr. Arthur Hurst opened a discussion on the

Treatment of Gastric Ulcer.

Medical treatment was, he said, handicapped at the start by tardy diagnosis. The average duration of the symptoms before treatment was about ten years. Better and earlier diagnosis depended upon the general practitioner. Indigestion that did not disappear rapidly on the application of simple measures was probably due to organic disease; if the nature of this disease was in doubt, the general practitioner should seek the help of a first-class radiologist. No gastric or duodenal ulcer would escape a radiologist with the necessary experience. Since X rays did not distinguish between an active and a healed duodenal ulcer, a biochemist should be requested to examine the stools for occult blood. A test-meal was a good auxiliary, but of less importance. Dr. Hurst believed that the pathogenesis of peptic ulcers lay in a diathesis; cases with many ulcers in the family history were the most difficult to deal with. The essential factor was the presence of free acid. Ten per cent. of all persons were born with a tendency to hyperchlorhydria, and the site of the ulcer depended upon the anatomy of the digestive organs. The exciting cause might be infection, most commonly from the mouth and less commonly from the throat, gall-bladder, and appendix. Of accessory exciting causes, especially of duodenal ulcers, the commonest was smoking, which increased the tendency to hyperchlorhydria; others were indigestible food and alcohol.

Though medical and surgical treatment were not opposed, surgical treatment was only indicated in perforation and permanent mechanical obstruction. In the absence of these conditions, medical treatment, if sufficiently strenuous and prolonged, would always cure even the largest ulcer, but patients should be prepared for a stay in bed of not less than four weeks and possibly of eight weeks. No measures should be relaxed until all spontaneous pain, tenderness, and rigidity had gone; until the most delicate test failed to detect occult blood in the stools, and until the X rays showed no signs of a crater. This criterion required at least four weeks, and an extra week should be allowed for safety. The second most important principle was to remove all septic foci; this demanded the help of the appropriate specialists. Finally, the patient must continue to observe the precautionary rules for the rest of his life.

Medical Treatment.

The basic principles of the method employed by Dr. Hurst were, he said, the avoidance of free acid and of mechanical irritation. The best means of avoiding free acid was to give hourly feeds of five ounces of milk or its equivalent through a tube; change of diet was introduced to avoid monotony. Drugs were of two classes: those which prevented the secretion of acid, such as olive oil, and those which neutralised it when formed, such as atropine; the latter was very valuable and was given in commencing doses of gr. 1/200, increasing to correspond with tolerance. Dr. Hurst's views on alkalis, he said, were unorthodox. Bismuth carbonate was not an alkali; sodium bicarbonate gave off carbon dioxide and caused undesirable distension, and, if given in excess, provided a most powerful stimulus to gastric secretion. He used sodium citrate, which also prevented milk from clotting; oxide of manganese, the dose of which could be regulated to keep the patient's bowels open; and the tribasic phosphate of calcium or magnesium—chiefly the former—which effectually prevented acidosis.

Cases with a certain amount of pyloric obstruction only required operation if the condition persisted after a fortnight's treatment. In addition to the routine, the stomach was emptied last thing at night; it was always found to be empty next morning. Even if operation were required, the treatment much improved the prospects of success by restoring the tone of the stomach. There was no danger of any ulcer becoming malignant except the rare prepyloric class; these should always be treated surgically.

Surgical Treatment.

Mr. H. S. Souttar agreed on the propriety of medical treatment in every case which was diagnosed when it should be, but said that few were. He quoted the statistics of surgical results published by the British Medical Association to show that 90 per cent. of cases were virtual cures; similar success had, he said, been achieved by Lord Moynihan, the Mayo brothers, Mr. A. J. Walton, Mr. Paterson, and himself. Operative treatment was no longer as serious a matter as it had been. A duodenal ulcer or a gastric ulcer in the neighbourhood of the pylorus was relatively easily dealt with by gastro-duodenostomy; for large ulcers involving the pancreas he relied on partial gastrectomy. Technique had been revolutionised by the introduction of local anæsthesia. He infiltrated the rectus sheath, made a mid-line incision, and injected the peritoneum on each side; then he raised the liver, passed the needle back into the retroperitoneal space and flooded the splanchnic area with about 60 c.cm. of ½ per cent. novocain. These injections took about four minutes and saved a great deal of time, and the patient was completely protected against any shock. Long and difficult operations for jejunal ulcer could be carried out entirely under local anæsthesia, and the patients escaped the usual after-effects. The economic advantage was heavily on the side of surgery, because the patient could go into the country a fortnight after gastro-enterostomy for duodenal ulcer and be back at work far sooner than if he had relied on medical treatment. Moreover, after about three months' moderately careful dieting he could, within any sort of reason, do what he liked. If a patient had to remain on diet for longer than that time, Mr. Souttar did not regard him as cured, and the real test between the physicians and the surgeons was what each meant by cure. There could be no doubt which was the most convenient method. The patient who had ample time and could afford to go in for careful dieting could allow himself the luxury of medical treatment, but the patient who realised that he had only one life and wanted to live it would prefer surgery.

Dr. ADOLPHE ABRAHAMS adduced against surgery the deplorable results of failure, which occurred even in the hands of the most capable surgeons. Surgery had the advantage when time was the most important factor, but could not cure the diathesis and therefore could not guarantee a cure.

Duodenal Feeding.

Dr. ERNEST YOUNG described Einhorn's method of duodenal feeding, which had now attained wide recognition in this country. A fine rubber tube was passed into the duodenum and retained for an average time of three weeks. The patient was fed every two hours. The keynote of the treatment was rest; the stomach was spared work and no food passed over the surface of the ulcer. The tube was easy to insert if it were simply passed into the stomach up to the 23 cm. mark, and the patient told to swallow it every ten minutes. The standard feed was an egg in 8 oz. of milk and 1 of lactose, but Dr. Young varied it with 8 oz. of Benger's Food and a teaspoonful of cream. Patients tended to gain in weight. The tube caused no discomfort after the second day at longest, and the pain of a gastric ulcer ceased after the first day. The pain felt in certain cases of duodenal ulcer was relieved by a dose of alkali after each feed for a few days. Liquid aperients were given when necessary, and severe anæmia was treated with injections of iron and arsenic. Patients were allowed to get up for toilet purposes and baths and when their beds were made, and there was little weakness after the three weeks. When the tube was removed a carefully graduated solid diet was commenced. The method was suitable for all cases of gastric ulcer except hour-glass stomach and those in which the X ray revealed pyloric obstruction. Duodenal ulcer took longer to cure by this means than by surgery, but the patient with even a large gastric ulcer could be back at work in five weeks. In after-treatment Dr. Young held a middle course between Dr. Hurst's views and Mr. Souttar's, putting his patients upon a carefully chosen but full diet.

Mr. W. H. A. DODD asked Dr. Hurst the correct treatment for perforation; whether after suture his normal régime was followed. He also inquired if any technique existed for passing a stomach tube painlessly.

Dr. JOHN REID confirmed from his practical experience the value of Einhorn's method. Of 25 cases treated, 24 were employed at active work after two years; none of them were people who could study their diet, and he regarded them as cured. The average increase in weight during the three weeks was 7 lb. A strong point in favour of the duodenal tube was that, if a second tube were kept in the stomach and the food introduced very slowly into the duodenum, the gastric secretion and acidity were steadily reduced, and after a fortnight it was practically impossible to obtain any free hydrochloric acid. He believed in withholding solids for a few days after the removal of the tube, and then introducing them gradually. He did not think that recovered patients could eat anything and everything, and warned them to "gang wary" and do everything they could to prevent recurrence of their ulcer.

Dr. J. J. SPIRA said that neither line of treatment was based upon the ætiology, which was unknown. Some cases with no hyperchlorhydria did well on alkalis, which must therefore have some other action besides that of neutralisation. Experiments showed that ulcers could be caused by innumerable agencies. He asked whether the chronic and the acute ulcers were identical. The high incidence, according to Dr. Hurst, could not be entirely due to a constitutional factor, but some factor must exist which turned an acute ulcer into a chronic one. Acute ulcers, with their sudden onset and virulent course, showed all the signs of a toxic or acute infective cause and of a systemic origin; chronic ulcers submitted to the usual evolution of chronic inflammatory processes and depended upon some unknown source of local irritation which was not due to hydrochloric acid nor to the ulcer itself. Research along these lines might reveal the factor which produced chronicity.

Dr. P. FOWLIE asked the correct treatment of jejunal ulceration following gastro-enterostomy. He deprecated any further surgical intervention. While admitting that alcohol had been used in the laboratory to cause ulcer, he inquired whether as a matter of experience it produced hyperchlorhydria in man.

Dr. H. H. SANGUINETTI asked what the comparative mortality was likely to be in the two methods. Until he was sure that there were enough surgeons to perform gastrectomy in all the cases that required it, he should prefer his patients to undergo gastro-jejunostomy, and he welcomed medical treatment for a large number of gastric ulcer cases.

Dr. MARIE CASSIDY said that she had long given up bismuth in favour of magnesia.

Dr. SYBIL EASTWOOD'S experience had shown her, she said, that ulcer in the lesser curvature of the stomach was generally very easy to cure by medical means. Duodenal and pyloric ulcers, on the other hand, though they could also be cured in this way, had a much greater tendency to relapse, and the patients were generally young people in robust health, who did a full day's work and found it more difficult to keep to a diet after treatment. From the psychological point of view, she suggested, it might be better to treat them by gastro-enterostomy when one course of medical treatment had been followed by a recurrence.

The CHAIRMAN, commenting on Dr. Hurst's statement that it was impossible to diagnose gastric ulcer without X rays, remarked that it was sometimes impossible to diagnose them with X rays. Moreover, it was possible with X rays to diagnose ulcers which were not there. The method could not be trusted to detect organic disease. Prepyloric ulcers—which he called duodenal—were sometimes malignant; it was difficult at operation to say whether they were malignant or not, but they were generally irremovable in any case. He advised the recovered patient to take no chances with his diet. Gastro-jejunostomy would, he said, cure even a large ulcer on the stomach. His figures for cure were also 90 per cent., but only a small proportion of the failures had been due to surgery. Four per cent. had died of intercurrent disease, and the jejunal ulcers were entirely the fault of the patients themselves.

Reply.

Dr. HURST said that the British Medical Association's statistics were full of fallacies. The answers had been obtained from 85 experienced surgeons for periods of four to nine years. If the results had been taken for the first nine years of each surgeon's career instead of the last, the mortality-rate would have amounted to at least 10 per cent. instead of 5, and this figure might be taken to represent the real mortality. The risk was too big to run willingly. The medical mortality-rate, on the other hand, was negligible. The gastro-jejunal colic fistula which sometimes resulted from operation for jejunal ulcer was a dreadful disaster, and many patients had to undergo repeated operations. Again, only 60 per cent. of the patients had replied to the questionaire; the remaining 40 presumably included the dead and a larger proportion of the unfit than the 60 per cent. Gastro-jejunostomy gave good results in cases of simple ulcer, but these were just the cases which did best on medical treatment, and those which would not respond to medical treatment would not respond to surgical. The original homes of this operation—Leeds and the Mayo Clinic—had, moreover, abandoned it. Bismuth and soda would mask the symptoms in a large number of cases, and had been the chief means of delaying the recognition of duodenal ulcer in London until about 1904. Alcohol between meals, as in cocktails, was absolutely disastrous, but weak whiskey and soda or light wine with a meal, if the patient had been well for some time, presented little danger.

Mr. SOUTTAR also replied.

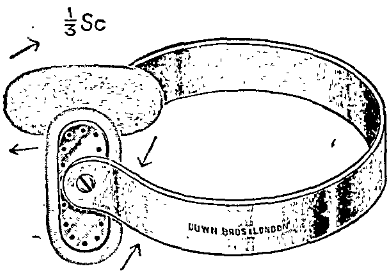
ROYAL SOCIETY OF TROPICAL MEDICINE AND HYGIENE: ÆTIOLOGY OF YELLOW FEVER.—In our report of the discussion following Prof. Kuczynski's lecture (THE LANCET, Jan. 25th, p. 187), Prof. Ledingham's statement "Diphtheroids . . . incubation" should read: "Diphtheroids, though rare as pathogens, were widely distributed organisms, and the occurrence of apparently saprophytic forms in healthy tissues had given considerable trouble in the interpretation of growths from virus-containing organs especially after long incubation"; and the sentence "To take one example . . . visible" should read: "To take one example, the organism of pleuro-pneumonia of cattle could be cultivated in purely artificial media with formation of colonies. Yet the virus-bodies which composed these colonies still remained, though microscopically visible, incapable of very accurate resolution."

Dr. Arkwright said: . . . He understood that, in the case of typhus, cultures which began as cocci were believed to change into something which, if it was not exactly . . . At the same time proteus and rickettsia appeared both to have a fundamental relationship to typhus fever. If the change from one to the other really took place somewhere, it was perhaps begging the question to criticise the change which was alleged to occur in vitro. It was necessary, however, for the observer to take care that his faith in the unity of the two types of organism did not carry him away into accepting . . .

New Inventions.

A NEW VARICOSE VEIN CLIP.

THE spring clip shown in the accompanying illustration has been designed to take the place of an assistant in the operation of varicose vein injection. It consists of two padded metal plates connected by a horseshoe spring which when applied over the site of an injection exerts sufficient pressure to prevent circulation through the vein while subsequent punctures are being made in other parts of the limb.

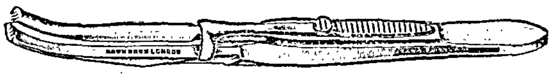


The instrument has been made for me by Messrs. Down Bros., Ltd., 21 and 23, St. Thomas's-street, London, S.E.

R. DAVIES-COLLEY, M.Chir. Camb., F.R.C.S. Eng.

NEW TONSIL-HOLDING FORCEPS.

THE advantages of the instrument, here illustrated, over others I have personally used are as follows: 1. The sliding, detachable, fastener prevents the teeth from biting through the tissue of the tonsil as by means of it one can judge the exact amount of pressure necessary to obtain a sufficient hold. 2. It never slips or tears away, it holds but does not bite through. 3. Made of stainless steel, it is solidly built, has strength to stand hard work and can be taken apart for cleaning. I have found it highly satisfactory in every way and can thoroughly recommend it.



The instrument is made by Messrs. Down Bros., St. Thomas's-street, London, S.E.

GEORGE VARIAN, M.D., B.Ch.

Reviews and Notices of Books.

MINOR SURGERY.

By FREDERICK CHRISTOPHER, M.D., F.A.C.S., Associate in Surgery at Northwestern University Medical School; Attending Surgeon, Evanston Hospital, Illinois. London: W. B. Saunders Company. 1929. With 465 illustrations. Pp. 694. 36s.

SEVERAL volumes on Minor Surgery have recently been published in England and it is therefore interesting to compare them with the latest views on the subject from America. This is a very good book. Its arrangement follows the usual lines except for the welcome addition of a long chapter designed for "The Surgical Intern." This is full of sound advice which may be read with profit, not only by the house surgeon, but also by his chief, and is mostly applicable to residents in our own hospitals. We do not, however, recommend the house surgeon in a London hospital to act on the suggestion that "it is generally desirable to address as many nurses as possible by their names."

The first chapters deal respectively with closed wounds, open wounds, foreign bodies, furuncles and carbuncles, burns, injuries by electricity, circulatory disturbances, and gangrene, while the rest of the book deals with injuries, infections, tumours, and deformities of the different regions of the body. Overlapping has been avoided with skill; "tennis leg" alone seems to be considered—and very well considered—under strains and also under injuries of the lower extremity. It is noteworthy that Dr. Christopher, when discussing antiseptics, everywhere ranks mercurochrome and iodine together, and even states that iodine has been given up as a first-aid dressing on a big railway system on the ground that it gets stale and if applied repeatedly may cause severe burns. He also reiterates most emphatically the doctrine that carbolic should never be used. If he is correct in this, most English general practitioners are steeped in heresy. The American idea of a fomentation seems to differ greatly from our own; here it is described as a large quantity of gauze soaked in warm, not hot, boric solution, and kept warm by an electric pad. In our experience electric pads are apt to produce burns.

Particularly good sections are those on the suture of wounds of face, in which Dr. Christopher is a strong advocate of closure by narrow bridges of adhesive plaster where possible; on the removal of foreign bodies, which removal he rightly emphasises should not be undertaken lightly; on breast tumours and their treatment; on the treatment of tattoo marks; and on local anæsthesia. The chapter on infections of the hand follows the lines laid down by Kanavel, who also contributes a foreword. The treatment of ganglions here advocated is rupture rather than incision. We cannot believe that the ideal treatment of a bromide rash is by intravenous injection of saline. The book is admirably printed on excellent paper and the illustrations are superb. There are few misprints and the English is excellent. The consulting surgeon and the practitioner will find much to interest them, while the house surgeon will find it invaluable.

INFLUENZA.

Etiologie et prophylaxie de la grippe. By R. DUJARRIC DE LA RIVIÈRE. Paris: Masson et Cie. 1929. Pp. 105 and plates. Fr.32.

THE writer of this monograph believes that, of the number of infective agents which have been considered as causes of influenza, only three merit serious consideration—viz., Pfeiffer's bacillus, the influenza filterable virus, and *B. pneumosintes.* Concerning the pneumococcus and streptococcus he has little to say; they are, in the words of Nicolle, "microbes de sortie"; they are found during the illness and are present in complications, but they are not the cause of the clinical disease. Most attention is given to Pfeiffer's bacillus. The chapter dealing with this organism constitutes, in fact, rather more than half the book, and is an excellent account of the life-history of the organism. The author leaves us with the impression that he considers it the most important of the three claimants to causation which he cites. The other two are, of course, more recent pretenders and there is less to be said, at the moment, for or against them. On the question of prophylaxis the author has progressive views. In addition to provision of hospital accommodation, isolation and immunological remedies such as vaccines during an attack, he advocates mobile laboratories for use during epidemics and more stringent regulations at the frontiers concerning quarantine to prevent the march of pandemics across the world.

The book is chiefly of value for its excellent account of Pfeiffer's bacillus. It is lucidly written and has a short bibliography. There are also numerous good photographs.

PHYSIOTHERAPY IN GENERAL PRACTICE.

Second edition. By E. BELLIS CLAYTON, M.B., B.Ch. Cantab., Director of the Physiotherapeutic Department, King's College Hospital, London. London: Baillière, Tindall and Cox. Pp. 231. 12*s.* 6*d.*

IN this edition over 50 pages have been added and some of the sections have been rewritten, notably those on scoliosis and fibrositis. The added matter is mainly concerned with a survey of treatment by ultra-violet light and various electrical currents. Dr. Clayton has not made any attempt to deal with the new material in detail, and those who wish to carry out his teaching in practice will have to refer elsewhere for detailed information about technique. There are now few points which do not find a place in this book, and the practitioner will find it a reliable guide when he wishes to superintend the conduct of a case under a masseur. The general impression given by Dr. Clayton's views is that they err on the side of caution. Little space is given to what is now commonly known as "manipulative" treatment, an omission that will need rectification in future editions as it is daily assuming a more prominent place in medical practice. The book is well produced.

RADIOLOGY OF THE NORMAL INFANT CHEST.

Das Thoraxröntgenbild des normalen Säuglings. By Dr. ERICH SAUPE and Dr. KURT EHLE. Lehmanns' Medizinische Atlanten, Band 17. Munich: J. F. Lehmanns. 1929. Pp. 41. M.6.

THIS volume of Lehmanns' well-known Atlas is a development of Dr. Saupe's "Thoraxröntgenbild im frühesten Kindesalter" (vol. 10 of this series, which appeared in 1925) and deals with the radiological appearances of the normal infant chest. It is based on 100 cases, after careful exclusion of pathological ones by painstaking clinical and laboratory investigation. The technical difficulties in this branch of radiography have been ably tackled by the authors, who have shown, in 16 good autotype reproductions from their radiograms, the fallacy of the generally accepted statement that the details of an infant's lung cannot be satisfactorily demonstrated by X rays. Their technique makes use of soft radiation and short exposures (effective kilovolts 35, milliampères 70; focal distance 70 cm.; exposure one-tenth sec. with screens), the recumbent child being maintained in a correct position with the head median. The considerable variations in the cardiac and mediastinal shadows and their causes, including slight enlargements of the thymus, are fully discussed with the aid of line diagrams. The lung detail at this age tends to be coarse and patchy, and, since it is almost entirely vascular in origin, shows considerable variation even in the same child at different examinations, according to the degree of filling of the vessels, which in turn depends on the phase and depth of respiration. In crying children this coarse patchy appearance is increased. The impossibility of inferring the presence of a bronchitis is emphasised. The translucency of the lung fields also shows marked variation, and we learn that an inclination of the head to one side suffices in infants to diminish the translucency of one apex through slight compression of the thin-walled bronchus. The monograph, though small, is of considerable practical value and, since it deals with a difficult and somewhat neglected subject with a refreshing absence of dogmatism, it will be welcomed by the radiologist. The references to literature are exclusively to continental publications and neglect the excellent work done in America, notably by W. W. Wasson and other workers in this field.

PHOTOGRAPHIC TECHNIQUE IN RADIOLOGY.

Die photographischen Grundlagen des Roentgenbildes. By Dr. RICHARD HERZ. Leipzig: Georg Thieme. 1929. Pp. 225. M.19.

THE author has confined himself to a straightforward description of the photographic side of the technique of radiography, but he has done his work exceedingly thoroughly and satisfactorily, with the result that the book is not only of use to beginners but also to advanced workers. Particularly interesting and useful is the chapter on the causes of faults and artifacts in films. It is a work which should be in the possession of every radiologist and, though technique may change, it will be many years before it is likely to be out of date.

SEWAGE DISPOSAL.

Principles and Practice of the Dilution Method of Sewage Disposal. By W. E. ADENEY, F.R.C.Sc.I., D.Sc., F.R.San.Inst., Curator and Examiner in Chemistry in the late Royal University of Ireland; Fellow and a former Vice-President of the Institute of Chemistry. London: Cambridge University Press. Pp. 161. 12*s.* 6*d.*

Sewage Disposal from Isolated Buildings. By G. M. FLOOD, B.Sc.Eng., A.M.Inst.M. & C.E., A.M.I.Struct.E., M.R.San.I., F.I.S.E. Manchester: Sutherland Publishing Co., Ltd. 1929. Pp. 257. 12*s.*

THE self-purification of polluted rivers and streams is becoming of increasing importance, especially in view of the establishment of new industries, such as the extraction of sugar from sugar beet and the manufacture of artificial silks. Such industries are being established on the banks of rivers which were formerly pure streams, with disastrous results to the fish and aquatic life. Dr. Adeney's work on questions relating to the oxygenation of water in rivers and estuaries has been of great value, and this volume not only gives a clear account of that work but includes a summary of the literature. The fermentative changes which occur when sewage is discharged to fresh water streams are described in a lucid manner. The researches in progress on the mechanism of the biochemical changes which occur during the fermentation of sewage matters in water are outlined, and the part played by saprophytic and nitrifying organisms in the purification of sewage and similar pollution made clear. Valuable sections are devoted to the rates of consumption of dissolved oxygen by sewage matters in fresh and sea waters. We have here a useful addition to the literature of the subject.

The question of sewage disposal is one of great importance from the sanitary point of view and often involves difficult problems with regard to the protection of water-supplies and the avoidance of nuisance. Mr. Flood has attempted to cover rather too much ground, and has introduced material of a highly technical character which is not germane to his object of giving "definite constructive information." The descriptions and constructional details of various types of plant are good and will prove useful to sanitary authorities. The illustrations are numerous and well selected and indicate clearly the arrangements necessary in the various conditions that may arise. The sections of the book which include elaborate accounts of various organisms found in sewage and alleged to take part in sewage purification might have been omitted without loss of value. Such information can be obtained readily and more accurately in special works on the subject. The descriptions and nomenclature of organisms are not always strictly accurate. Chapter XI., devoted to the design of filters, contains much useful information, but the capacities recommended are much underestimated and engineers constructing plants would be well advised to make more liberal provision.

Collection of Published Papers.

Published Papers by Members of the Staff of the Middlesex Hospital Medical School: 1928–29.

THIS collection of over forty papers published during the last academic year contains valuable contributions to medical science, many of which have previously appeared in these pages. From the Bland-Sutton Institute of Pathology come contributions on the subject of malignant disease, such as Prof. J. McIntosh's paper on the Rous Tumour and Its Bearing on the Virus Theory of Cancer, and that on Giant-cell Tumours of Bone in a Fowl, by Dr. S. L. Baker. The biochemical department contributes many valuable papers, such as that on the Œstrus-producing Hormone, by Prof. E. C. Dodds and three of his colleagues, while the department has also collaborated in a big piece of team-work research with Mr. G. Gordon-Taylor, Mr. R. V. Hudson, and Dr. L. E. H. Whitby on the Remote Results of Gastrectomy. From the Cancer Research Laboratories and Department of Physics there are several papers on the effects of radiation, of which that by Prof. S. Russ and Miss G. M. Scott on the Differential Action of X Rays and Gamma Rays upon Some Living Tissues is an example. The Physiological Department is represented by some interesting studies, notably that by Prof. Swale Vincent and Mr. J. H. Thompson on the Rôle of the Thyroid and Parathyroid Glands in Vaso-motor Reflexes. Lastly, there are many important contributions on clinical medicine and surgery, of which Dr. Shirley Smith's paper on the Pain and Discomfort of Congestive Heart Disease, and Mr. Sampson Handley's several papers on breast carcinoma may be mentioned. These few examples serve to show that the staff of the Middlesex Hospital continue to regard research as one of their most important duties. We must repeat the plea made in previous years—that such a collection deserves a more permanent and fitting production than the conglomeration of reprints of various shapes and sizes assembled in this volume.

JOURNALS.

JOURNAL OF PATHOLOGY AND BACTERIOLOGY. Vol. XXXIII. Pp. 1–232. January, 1930.—The production of staphylococcal toxin, by F. M. Burnet (Melbourne). *S. aureus* does not produce hæmolysin in broth cultures unless the cultures are incubated in an atmosphere containing excess of CO_2. The white variants produce hæmolysin freely.—The pathogenesis of and propagation of the virus in experimental poliomyelitis, by R. W. Fairbrother and E. W. Hurst (London). The disease begins as a primary degeneration of nerve-cells with an inflammatory reaction of the connective tissue, not as a meningitis. After intracerebral inoculation the virus spreads along the axis-cylinders downwards, and owing to the greater susceptibility of the lumbar nerve-cells symptoms usually appear first in the legs; the symptoms are therefore no guide to the spread of the virus or to the point of entry. Virus is present in greatest amount in the neighbourhood of the lesions in the cord; it survives for only a few days in the cerebral cortex and hardly ever reaches the cerebro-spinal fluid.—The action of certain dyes on the bactericidal activity of normal serum and on hæmolytic complement, by J. Gordon (Leeds). Congo red and other dyes prevent the hæmolytic and bactericidal actions of serum; the mechanism is not yet explained.—Dysentery toxin (Shiga), by C. C. Okell and A. V. Blake (London). Active preparations of Shiga toxin may be obtained by filtering broth cultures after about a fortnight's growth, and from this filtrate the toxin may be precipitated by ammonium sulphate. In the early stages of growth the toxin is held within the bodies of the healthy bacilli; afterwards autolysis gradually disintegrates the bacilli and sets free the toxin into the medium.—Generalised osteitis fibrosa with parathyroid hyperplasia, by A. M. Drennan (Dunedin). A typical example in a woman of 63 with a large parathyroid adenoma.—Miliary aneurysms in the brain, by F. H. K. Green (London). Small aneurysms are found only in a small proportion of deaths from cerebral hæmorrhage, and only where the media of an artery is grossly involved in atheromatous degeneration. The anatomy of two examples is minutely described.—The pathology of disseminated encephalomyelitis of the dog (the "nervous form of canine distemper"), by J. R. Perdrau and L. P. Pugh (London). The disease has nothing to do with distemper; its relation to the "hysteria" of dogs is doubtful. There is a characteristic infiltration of the meninges and perivascular spaces of the brain with small round cells, and in four instances demyelination of the type seen in acute disseminated sclerosis was found.—Oat-celled tumours of mediastinal glands, by J. B. Duguid and A. M. Kennedy (Cardiff). Barnard showed that most oat-celled tumours of the chest are carcinomata of bronchi; this is not invariably the case, for a few arise from the mediastinal glands.—The changes in the mammary gland preceding carcinoma, by A. A. Charteris (Glasgow). Most cases arise from epithelial proliferation in the ducts.—Further experiments on the carcinogenicity of synthetic tars and their fractions, by C. C. Twort and J. D. Fulton (Manchester). The activity of a number of artificial tars varies with the substance used as a source and with the temperature of distillation; it may be greatly reduced by oxidation or reduction, and may be concentrated by fractional distillation.—Note on the fermentation of starch by certain hæmolytic streptococci, by F. W. Andrewes (London). Some strains ferment, others do not; the power is not related to pathogenicity.—Spontaneous tuberculosis in the guinea-pig, by A. Stanley Griffith (Cambridge). Seven examples of this rare condition, which may be caused by human bovine or avian bacilli.—The specificity of active immunity against snake venoms, by C. H. Kellaway (Melbourne). The specificity of the active immunity induced in guinea-pigs by fresh or formalised venom depends on the zoological relation of the snakes involved and the constitution of the venom, the former being more important. The specificity is not so clearly marked as with the corresponding antitoxic sera and immunisation with, for instance, copperhead venom confers a considerable resistance to tiger snake venom.—The late results of intravenous injection of colloidal iron, by D. F. Cappell (Glasgow). The iron is first taken up by the reticulo-endothelial system generally and afterwards redistributed, accumulating in the liver, spleen, and lymphatic glands. Nothing like hæmochromatosis is produced.—Cholelithiasis in the insane, by G. W. T. H. Fleming (Dorchester). At the younger ages (20 to 40) gall-stones are more frequent in the insane than in an average hospital population.—The thermal death-rate of the bacteriophage, by S. H. Nanavutty (London). The fatality of heat to bacteriophage varies with the suspending medium. The mode of death suggests that the individual units vary in their heat resistance.—Titles of the other papers are: An unusually large adenoma of the liver, by R. G. Dhayagude (Bombay).—On testing *C. diphtheriæ* for virulence by the intracutaneous method, by W. Mair.—A colour-index ratiometer, by F. T. Grey.—The prognostic value of protein determinations of the cerebro-spinal fluid, by F. T. Grey.

THE LANCET.

LONDON: SATURDAY, FEBRUARY 1, 1930.

THE BACTERIOLOGY OF INFLUENZA.

THE publicity given to recent work at Chicago on the bacteriology of influenza has again turned attention to this problem. It has been maintained by some epidemiologists that the disease clinically known as influenza is but part of a much more comprehensive wave of morbidity which constitutes the true influenza. It seems a pity that the same name should be used for such distinct ideas. Whether this conception is correct or not it is obviously of advantage to discover the exact microbic infection in the cases of disease, and a great deal of work has, of course, been directed towards this end. The similarity of the curves of rise, fall, and recurrence of influenza in 1889–90 and 1918–19 epidemics, and (as far as records go) in previous epidemics, suggests that some uniform factor was at work. The forms of the waves and the type of disease were apparently independent of climate, season, and country, though the rate of mortality was probably influenced by the weather to some extent. There is evidence that scattered cases of influenza-like disease of moderate severity have preceded the two great pandemics of the last 40 years. The first wave of the epidemic is characterised by cases of severe acute fever, often with only slight signs of localisation in the upper air passages. After the rapid rise and fall of this wave and an interval of one or two months, the second wave appears with a much more definitely bronchitic and pneumonic form of disease. Later, a further wave or waves occur with catarrhal or pulmonary cases, of irregular but usually lessened severity. How far epidemics confined to a single town, country, or continent should be considered to belong to the same type as pandemic influenza is undecided.

It is generally acknowledged that influenza is a disease spread by infection, but the symptoms of patients, especially at different periods of the epidemic, are very diverse. The clinical diagnosis of individual cases is notoriously unreliable and comparative certainty is only reached in the presence of an epidemic. The change in character of the symptoms and lesions from one period or wave to another needs some special hypothesis to explain it, in whatever category of causes it is sought. Whether the primary causes of the epidemic are conceived as external to the human body and its invading microbes, or as concerned with the infecting micro-organisms themselves, this changeability undoubtedly is an essential feature. Inquiry has been chiefly directed to finding out whether changes in the bacterial agents alone may not be a sufficient reason for the variation in the disease and the course of the epidemic. Three main kinds of micro-organisms are known to infect and invade the tissues in many cases of influenza and have been inculpated in turn by bacteriologists. These are the *Bacillus influenzæ* of Pfeiffer, various streptococci, including the pneumococcus, and *B. pneumosintes*. The last, though probably related in some way to certain outbreaks of so-called influenza, has only occasionally been recognised, and its claim to importance rests on its association with a limited number of cases of the disease. The pneumococcus undoubtedly may be a serious infectant but has never been held to be the sole primary infective agent. Various strains of the streptococcus are very frequently found in infections of the air passages in influenza, but particular influenzal types have not been widely recognised, though in some outbreaks—especially in the more severe phases—streptococci have been held responsible for broncho-pneumonic lesions. The claim by FALK and his colleagues[1] to have identified the streptococcus which caused the epidemic in Chicago in 1928–29 does not, so far, carry conviction but cannot be fully discussed till a more complete account of their work is accessible.

All the above-mentioned bacteria have often been found acting in company as pathogenic agents. Their relative prevalence and claims to importance are well and critically reviewed by Dr. W. M. SCOTT in Vol. II. of the "System of Bacteriology," which is being issued by the Medical Research Council. *B. influenzæ* is the only bacterium which has sufficiently often been found in intimate association with the disease processes to justify the claim that it is the essential pathogenic organism of influenza. Its rôle is much disputed, however, and the first point to decide in discussing the ætiology of influenza is whether a virus infection predisposing to a bacterial secondary invasion must be invoked to account for the rapid spread and high infectivity of the disease and its other features. There is little doubt that *B. influenzæ* and streptococci gain in pathogenicity during an epidemic and it is perhaps gratuitous to import an unproven virus to account for the increase of susceptibility to these infections. It would be necessary to assume that as the hypothetical virus spread over the world the secondary agents accompanied it, unless it were thought that these latter were ubiquitous and in each case assumed increased virulence under the influence of the virus. Such an explanation would not be complete, since the virulent secondary infections are almost certainly sometimes passed from patient to patient. It seems simpler to suppose that occasionally a bacterial agent assumes increasing virulence and by passage through many susceptible subjects further adds to its invasive and pathogenic powers and becomes associated with fresh colleagues in its course. The rapid transference is aided by the increased bronchial secretions and their expulsion and dissemination by coughing. Such an increase in pathogenicity of the infective agent is a necessary hypothesis in any attempted explanation of influenza and is known to occur to some extent in experiments with *B. influenzæ* and streptococci. It is no greater assumption to suppose increased virulence of these bacteria than of an unknown virus which would also be required to bring about increase of virulence in several kinds of bacteria. In estimating the relative probability of such occurrences one must take into consideration that the *B. influenzæ* is known to be remarkably variable in its cultural characters and toxicity. Though described by PFEIFFER in 1892, the methods required for its identification and its cultural needs have only been completely understood in the last eight or nine years as the result chiefly of the work of FILDES[2] and TJÖTTA and AVERY (1921),[3] on the X and V accessory growth factors and the new method of selective culture by the use of aspergillin demonstrated by FLEMING[4] last year. The culture and isolation of *B. influenzæ* was not so readily obtained in 1918 as at the present day and this may explain its apparent absence in some outbreaks.

PROFESSIONAL PRIVILEGE: THE QUESTION OF DIVIDED LOYALTIES.

A South African journalist has gone to prison sooner than disclose information which came to him under a promise of secrecy. He had to choose between two loyalties—a dilemma, not entirely academic, which the medical profession has sometimes to encounter. The journalist had written an article on the subject of an alleged illegal lottery; he was thereupon questioned by a magistrate under the Police Administration Act, presumably with a view to criminal proceedings in which his evidence might have been material. He refused to answer the magistrate's questions. No doubt it was pointed out to him that journalists enjoy no form of professional privilege under the law, and that every citizen owes the State the duty of assistance in the detection of crime. He preferred, however, to remain faithful to his promise, and he left it to the police to carry out unaided their function of discovering a criminal offence. It happens that not long ago a similar incident occurred in America. A Washington newspaper had been dealing with alleged breaches of the prohibition laws. Three of its reporters were summoned before a grand jury and were asked as to their source of information. They, too, declined and were sentenced to imprisonment. Perhaps it is unnecessary to point out that the jurisdiction in both the South African and the Washington incidents is not one which operates in England. Apart from a remarkable clause in the Official Secrets Act of 1920 (an unobtrusive survival of the wide powers entrusted to the executive during the war), there is no power in England for the police or grand jury to interrogate witnesses at large under threat of imprisonment for refusal to answer. It may, however, happen at any time that a medical practitioner may be pressed in the witness-box to disclose his patient's confidences entrusted to him under a pledge of secrecy not less binding because not formally expressed or legally sanctioned.

The Washington journalists, it seems, have served their imprisonment; they have maintained the principle for which they stood and their case is ended. It is not clear whether the South African journalist is imprisoned indefinitely or not. It seems a case in which the prospect of appeal is dubious, but it is said that an appeal is being undertaken Publicity will bring public opinion to bear on one side or the other, and in the long run the law must conform to public opinion. If, in an extreme case in England, a doctor refused to answer questions in the witness-box on the ground of professional privilege, would public opinion support him? The court, jealous of its authority, would not lightly pass over what it would regard as an act of disrespect. Wilful disobedience to a subpœna not only means attachment for contempt of court, it also involves possible liability to the party at whose instance the witness summoned for any damages which that party can w that he has suffered by the loss of the evidence. latter liability, naturally, would not arise if the uant called the doctor as a witness, because ivilege is in the interest of the patient, and the can absolve the doctor from the duty of secrecy. The general question of medical privilege has never been pressed upon popular notice; for this purpose some such sacrifice may be required as has lately been made in the two cases under discussion. The legal profession is allowed by law a complete privilege; the explanation is that people cannot get justice unless they can be sure of frank consultation with their legal advisers. The medical profession is allowed by law no privilege at all, though frank consultation between patient and medical adviser is obviously an essential condition for the treatment of ill-health. The public ought to consider whether the tradition of medical secrecy deserves support. It should do so without the excitement of seeing medical martyrs volunteering for prison for the sake of principle.

◆

THE CASE AGAINST THE WIDAL TEST.

IT appears from various reports that a modification of the agglutination test of Widal is likely to have a wider and more useful application in the diagnosis of typhoid fever than did the original test, and that the Widal though practised with a perfected technique is still open to much criticism. It fails in three respects—namely, in the early serological diagnosis of typhoid fever; in the previously inoculated individual; and in the persistently negative cas and it has never held out any hope of detecting t carrier. That a negative Widal reaction is frequen a most misleading report, is an opinion widely h among clinicians. That it may become positive the third or fourth week of disease is of comparativ little value to them. Laboratory workers, howe must have criticism based on unquestionable diagn before deciding to abandon the test. A series of c reported by FELIX[1] in which cultures were made, a larger series by PIJPER[2] in which cultures complement fixation were done, amply confirm general impression. In PIJPER's series, assumi dilution of 1 : 40 as diagnostic, then out of 199 sam of serum (representing 120 cases) only 160, or 80 cent., were positive, while if 1 : 80 be taken as crucial dilution, only 102, or 51 per cent., were posit Or analysing his figures from the more pract clinical point of view, only 72 cases, or 60 per cent., positive in a dilution of 1 : 40 at the time of the serological examination, which is the time when clinician really needs help. There is clearly here for improvement greater than that afforde the perfection of quantitative standardisation as is achieved by Dreyer's technique. Next in pra importance at the present time is failure of the test to afford help in the inoculated person. has stated,[3] and is supported in this belie numerous authorities that "it is now estab beyond all question that after the agglutinins are produced by vaccination have already disap from the blood, they can reappear after many under the non-specific stimulation of some typhoid disease as an anamnestic reaction." the interpretation of a positive Widal in a previ inoculated person is always open to doubt. The t failure is in the persistently negative case, whose se at no time during disease or convalescence give positive agglutination test. Attention has be drawn to these cases by FELIX, PIJPER, and BURNET, and in our last issue by GARDNER, HOBSON, and STENHOUSE.[4]

[4] Gardner, A. D., Hobson, F. G., and Stenhouse, G.: THE LANCET, Jan. 25th, 1930, p. 182.

Independent attempts to solve these difficulties were made by FELIX and by PIJPER; the former succeeded by means of his "qualitative receptor analysis," the latter by an application of complement fixation. Both these substitutes achieve the same ends. They enable an earlier diagnosis to be made; they bring to light the nature of the disease in the persistently negative case, and they circumvent the difficulty presented by previously inoculated individuals. Further, PIJPER has shown that carriers react positively to complement fixation, and by Felix's method the whole enteric group can be differentiated in one dilution without titration of the serums. The principles of complement fixation are sufficiently well known to need no introduction. Qualitative receptor analysis, dependent on the detection of "O" (or group small-flaking agglutinins) and "H" (or specific large-flaking agglutinins) is still somewhat of a mystery. In its simplest terms it means that instead of the typhoid bacillus possessing one kind of agglutinogen only, giving rise to one kind of agglutinin, it may be, and usually is, composed of two antigens the "O" or group and the "H" or specific. These are named in German *Hauch* and *Ohne Hauch* from the spreading and non-spreading growth of *B. proteus*, in which organism these antigens were originally discovered by WEIL and FELIX. "O" antigen gives rise to "O" agglutinins only; "H" antigen gives rise to both "O" and "H." Now in the majority of cases of typhoid, the "O" agglutinin appears in the serum at an earlier date in the disease than the "H" form, and it is the latter type of agglutination which an ordinary Widal test detects. It does so because nearly all test suspensions consist of "H" forms of typhoid bacilli. Thus the useful early appearing "O" agglutinin is entirely missed. In inoculated persons the anamnestic reaction is accompanied by "H" not by "O" agglutinins, therefore the appearance in a subsequent fever of "O" agglutination indicates that the disease really is an enteric fever. It must be pointed out, however, that "O" agglutination is a group reaction—i.e., it is common to typhoid, the paratyphoids, and Gaertner infections, and further differentiation within the group may have to wait till "H" agglutinins appear; but that the disease is due to a bacillus of the group will be certain, for the small flakes are not provoked by other fevers. It will be seen that in the inoculated person differentiation within the group may be impossible. The further discovery by FELIX of the culture known as *B. typhosus* 901, which is extremely sensitive to "O" agglutinins, and remains so in subculture, has enabled practical use to be made of this analysis. This work has been repeated and confirmed by BURNET, PIJPER and STUART and KRIKORIAN. The exact relation which these antigens bear to rough and smooth (somatic and flagellar) and to the chemically isolated antigens has not yet been established.

An example to which we have already referred of the persistent negative Widal reaction in the case of typhoid fever reported by GARDNER, HOBSON, and STENHOUSE, illustrates the usefulness of the new method. A patient with a clinical picture of severe typhoid fever had Widal tests done on the nineteenth and twenty-fifth days of the disease. On both occasions they were negative but on the second occasion the serum was tested for "O" agglutination, and a blood culture was made. The "O" agglutination proved positive (1 : 500 with living saline suspensions of *B. typhosus* 901) and a non-motile typhoid bacillus was isolated from the blood. Had the "O" agglutination test not been done in this case, the diagnosis would still have remained in doubt till the bacillus became motile. The authors, as a result of their experience, recommend "O" suspensions to all pathologists and clinicians. *B. typhosus* 901 is in the National Collection of Type Cultures; and Dr. GARDNER has prepared standard suspensions from it at Oxford.

Annotations.

"Ne quid nimis."

HEALTH OF THE ARMY IN 1928.

THE annual report on the health of the Army, which has just been issued,[1] is signed by Lieut.-General H. B. Fawcus; it appears a month earlier than last year, is of the same size but costs sixpence more. It tells of improving conditions; influenza was almost absent, malaria was decreasing, in India the malarial sickness-rate fell from 138·8 to 91·3 per 1000, and the sick daily from 3·40 to 2·40. In the Army at home and abroad there were 183,333 men, of whom per thousand 426·2 (last year 467·7) were admitted to hospital, 1058·9 (1106·7) were treated as out-patients, and 38·98 (42·79) were daily under treatment. There were 9464 officers, of whom 29 (10) died from injury. There were fewer cases of disease this year among cadets, and diphtheria was the only serious preoccupation in the schools for boys; Schick testing and immunisation approved themselves after experience, and all new entrants to the schools are to be thus dealt with in future. Among the men, the chief causes of admission to hospital were venereal disease, 30·3 (49·1), malaria, 35·7 (49·5), and tonsillitis, 33·3 (33·8). The death-rate was 2·36 (2·42), the chief causes being: injuries 133, pneumonia 59 (73), "other digestive diseases" 44 (43), tubercle 30 (32), "other infective diseases" 25 (20), suicide 25 (38), tumours 24 (9), enteric group 20 (15). The invaliding rate was 9·06 (11·43), chiefly due to disease of the middle ear and to tubercle, 207 (213) cases, 1·13 (1·08); 34 were invalided for hysteria. The disease causing most loss of service is gonorrhœa; the average case seems to last 58·5 (53·1) days. Scabies cases were cured in a day less than last year, 7·16 days. Dysentery is in India mostly bacillary, 80 per cent.; immunisation by bilivaccine was thoroughly tried, but results were conflicting. Enteric cases were 30 at home, 20 of them in one epidemic at Aldershot, cause not stated. About 98 per cent. of the Army—officers, men, women, and children—is protected by inoculation. Single doses of the protective vaccine are thought ineffective; it seems to be the idea that cases are mostly spread by carriers. Malaria, 6550 (9204) cases, 35·7 (49·5) has greatly decreased, the figures for India are 5142 (7723), 91·3 (138·8). For their protection troops are sent to the hills during the malarial season, barracks and houses are mosquito-proofed with copper wire netting, and mosquito-breeding places are controlled. At a new station, Changi, near Singapore, the anopheles group are so reduced that it is thought mosquito-proofing of the new barracks will be unnecessary. Paris green powder, harmless to larger animals, is cheaper than oil for destroying larvæ. As to treatment, plasmochin has been found to prevent relapse better than any other drug used. Treatment of pneumonia with rectal injections of permanganate was strongly approved in Cairo, but not at Woolwich. Tubercle is less, but there is no table of the prevalence at ages, as in the last R.A.F. Report.[2] Sandfly fever was more frequent. As appendicitis cases come to notice quickly, results are good; 1144 cases with but

15 deaths. Of Mediterranean fever one case was definitely diagnosed, but over 900 occurred in Malta in 1928. Of knee cartilages, 202 internal were removed and 6 external; all the patients went to duty. Twenty-four gastric ulcers were operated on but six died; 28 duodenal with one death. Extensive improvements are being made in barracks, married quarters and hospitals, also in feeding the men and cooking for them. The Thames flood of January, 1928, wrecked two museums of the R.A.M.C. College, but they are being restored. Pathological laboratories are being put into all Indian hospitals. Four laboratory-diagnosed enteric cases are noted, one thought to be sandfly fever, one broncho-pneumonia, one nephritis, one jaundice. Of the malaria cases, 72 per cent. were benign, 14 malignant tertian, 1/10 per cent. quartan, only 13 per cent. were not microscopically diagnosed. At Hong-Kong, in 50 obstinate jaundice cases, half were found to have ascaris, which being removed they recovered. A single case of scurvy was diagnosed in London, but no signs or symptoms are mentioned. A new first-aid packet is being prepared. There is much of interest in this report.

BERI-BERI IN A WHALING EXPEDITION.

It might have been expected that, with our present knowledge of the ætiology of beri-beri, a well-organised whaling expedition would be able to avert this calamity. That this is not so is evident from a paper in *Tidsskrift for den Norske Laegeforening* for Dec. 15th, 1929, in which Dr. Johannes Nissen, medical officer to a Norwegian whaling expedition, discusses a state of affairs which gave him good reasons for the greatest anxiety. It may be added, by way of preface to his paper, that the revival of the Norwegian whaling industry during the last two decades is almost the only bright spot in the financial situation of a country suffering profoundly from post-war commercial depression. Thousands of Norwegians depend on the whale for their living, and any factor interfering with the smooth running of whaling expeditions may be a serious matter to the whole country. Dr. Nissen was attached to a South Shetland whaling expedition in 1927–28. In the middle of March, 1928, beri-beri broke out on a boat, *Pythia*, which was stationed a day's journey from Deception Island, where Dr. Nissen was working. Early in April three of the crew had to be landed and admitted to hospital on the island, one of them dying two days after admission. There were altogether 37 well-defined cases of which five were severe. There were also 14 other cases of early beri-beri in which objective signs of the disease were not demonstrable; the men complained of lassitude, tenderness of the muscles of the legs, palpitation of the heart, and a feeling of ants creeping on the skin. In the well-defined cases the abovenamed symptoms were followed by the development of œdema about the ankles and front of the tibia, by anæsthesia and absence of the patellar reflex, and in five cases by pareses. The dietary of the expedition was rich (too rich in Dr. Nissen's opinion) with three hot meals a day; peas, salt meat and pork twice a week, pork and beans twice a week, a soup of salt cabbage and carrots once or twice a week, stewed dried apricots or prunes, salted and dried fish once a week, "betta" soup or salt mackerel or herring once a week, tinned meat twice a week, and from the new year onwards fresh pork once a fortnight. Whale meat was occasionally eaten, and potatoes every day. But while five of the seven boats of the expedition were provided with wholemeal bread, in addition to ordinary fine rye bread and wheaten bread, or a mixed loaf containing rye and wheat flour, the bread eaten on the *Pythia* was made from finely sifted rye flour of poor quality. Dr. Nissen is inclined to trace the outbreak of beri-beri chiefly to this but also to several other causes. In addition to the lack of wholemeal bread, he noted that the sleeping quarters of the crew were damp and dirty as compared with those of the other ships. He also found that the potatoes were in an unsatisfactory state, and it would seem that on a ship's voyage from Norway, through the tropics, to the Southern Hemisphere, some of the crew are employed almost all the time in attending to sprouting potatoes which, after they have been stripped two or three times of their sprouts, have presumably lost most of their B-vitamins. This difficulty cannot be got over by provisioning a ship with potatoes in a South American or South African port, for the Norwegian sailor dislikes the insipid and sweet taste of potatoes grown south of the Equator. Dr. Nissen, therefore, suggests that the quarters on board ship reserved for food storage in the ships of whaling expeditions should be subject to much more stringent regulations than at present, and that, as far as potatoes are concerned, a cool place must be provided, the temperature of which can be kept only a couple of degrees above freezing-point. Yet another recommendation is that the rich dietary of the present régime should be simplified, For, as various observers have remarked, it is the fat man rather than the lean man who develops beri-beri. Dr. Nissen adds that medical officers of modern whaling expeditions often find dyspepsia the most frequent of all the ailments on board ship. He concludes: "The dietary of our fleet should be completely changed."

CORONARY THROMBOSIS.

Dr. S. A. Levine's review[1] of the Clinical Features of Coronary Thrombosis is based on a series of 145 cases, reports of which are given in full. Forty-six of these cases eventually came to autopsy and the pathological findings are considered in detail. Most of his patients had suffered from ordinary angina before the onset of coronary thrombosis, but some had apparently enjoyed unusually good health up to the moment of the attack, and had indulged actively in sport or other forms of vigorous physical work. In 34 cases glycosuria was present, and of these a considerable number were actually diabetic. Fifty-eight patients were known to have suffered from high blood pressure and in several others sclerotic changes were found in the retinal arteries. In some instances there appeared to be a definite familial tendency to hypertension or coronary disease. Neither syphilis nor rheumatic infection seemed to be directly related to the condition. The disease was much more common in males than in females, and the average age of the group was 57·8 years.

The pain of coronary thrombosis differs from that of ordinary angina in its duration and in not being relieved by nitrites, since the attack itself is usually associated with a sudden fall in blood pressure. After the attack the heart sounds are weak, and auricular fibrillation, ventricular tachycardia, gallop rhythm, and other disturbances of the cardiac mechanism are apt to be present. A pericardial friction rub may be heard. In addition to these purely cardiac manifestations, shock, vomiting, and dyspnœa serve to distinguish coronary thrombosis from ordinary angina, while the infarction often gives rise to a slight rise of temperature and a leucocytosis in the blood. In fatal cases death may be due to ventricular fibrillation, shock, or rupture of the heart, while patients who survive the early complications are liable to manifest a progressive type of congestive heart failure. Fifty-three per cent. of the patients in Dr. Levine's series died as the immediate result of the attack. He deals very fully with the electrocardiographic signs of coronary thrombosis, and illustrates his paper by numerous records, but he points out that the characteristic changes are not present in all cases. As regards treatment, he advocates avoidance of cardiac stimulants when the systolic pressure does not fall below 100, and prefers to concentrate attention entirely on the relief of pain by adequate doses of morphia. When, however, the patient is in a state of collapse, caffeine.

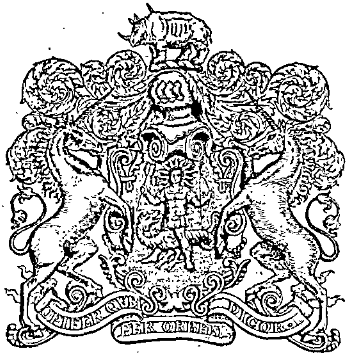
---

[1] *Medicine*, Sept., 1929. Obtainable in England from Messrs. Baillière, Tindall and Cox, London.

adrenalin, or strophanthin may be helpful, and in dealing with the important complication of ventricular tachycardia quinidine is called for. In 39 of the 46 cases (85 per cent.) in which an autopsy was obtained, the vessel involved was the anterior descending branch of the left coronary artery. Less commonly there was a diffuse arterio-sclerosis involving the smaller coronary branches and leading to chronic fibrous myocarditis. Dr. Levine suggests that this group probably provides most of the clinically atypical cases in which infarction is unaccompanied by pain. In two cases only was occlusion in the right coronary artery revealed post mortem, and it is interesting to note that in neither of these did the patient complain of pain.

OPIFERQUE PER ORBEM DICOR.

THE motto accompanying a coat-of-arms has sometimes very little obvious connexion with the blazon or with the status and occupation of the person or persons to whom it was granted. It is rare, indeed, to find a motto so appropriate as that of the Society of Apothecaries of London. It completes the achievement, not only in furnishing a clue to the meaning of the escutcheon, but also in showing in a very definite sense the aims and objects of the ancient guild to which it was granted. In a paper recently read before the Historical Section of the Royal Society of Medicine[1] Dr. T. Vincent Dickinson, a past Master of the Society of Apothecaries, gave some interesting information and details of the Armorial Bearings. These were devised, he said, by William Camden, Queen Elizabeth's celebrated Charenceaux King of Arms, in 1617 soon after James I. had finally separated the Apothecaries from the Grocers and Pepperers at the instance of Gideon de Lame and granted them a Charter of their own. The details and motto are founded on the episode of Daphne in Ovid's Metamorphoses. Apollo, who has just killed the gigantic python, "Qui modo pestifero tot jugera ventre prementem stravimus innumeris tumidum Pythona sagittis" is depicted with radiant head denoting his sun godhead with a golden bow in his left hand and an arrow in his right, striding over the prostrate foe. It seems to indicate an energetic and combative spirit and points the moral that the occupation of the Apothecaries was not merely mechanical like that of the Barber-Surgeons, nor purely studious and abstract like that of the Physicians, but was an Art founded on action with a firm grasp of the weapons wherewith to combat disease and an ever ready recourse to the means of doing so. Ovid states that the first of Apollo's loves was Daphne, daughter of Peneus, "a love that no blind chance brought to him but Cupid's heartless wrath." Apollo, having just killed the Python, twitted Cupid: "Wanton boy, what hast thou to do with warrior's arms?" And Cupid's answer was: "Thy bow may pierce all else, but mine shall pierce thyself." Thereupon from the quiver which held his arrows he drew forth two shafts of diverse powers; the one banishes love, the other creates it. That which creates love is made of gold and has a bright keen point, but that which banishes love is blunt and has a barb of lead at the tip. Now this latter did the God Cupid fix in the heart of the nymph Daphne, the daughter of Peneus, the River God, but with that other he wounded Apollo to the very marrow, piercing all his bones. Straightway Apollo was love-sick but Daphne fled from the very name of lover and took solace in the gloom of the forest. When Apollo pleaded his suit, faster than the light wind she fled away and paused not at his words as he tried to call her back. "O Nymph! O daughter of Peneus, I pray thee stay! Rash one, dost thou not know from whom thou art flying? Jupiter is my Sire; medicine, too, is my discovery, and I am called all the world over the Bringer of Aid. (*Inventum medicina meum est, opiferque per orbem dicor.*) For the virtue of all herbs are at my bidding, but woe is me: for love may not be cured by any herbs." But Daphne prayed to her father to change her fatal beauty and she became transformed into a laurel. Even in this shape Apollo loved her still. "Now since thou canst not be my wife, thou shalt be my tree. My locks, my lyre, my quiver shall wear thee ever, O laurel tree! and even as my brow is ever young with locks unshorn, so do thou likewise keep evergreen for all time the beauty of thy foliage." The motto is an exortation to all descendants of Apollo, the discoverer of Medicine, bringers of help, that they too may keep evergreen for all time and that each member of the craft may follow his footsteps and example and ever seek more and fuller knowledge of that healing Art which can assuage all ills but that of love, and gird their loins and discharge their shafts against the dragon of disease so that when the victory is ours each may say with truth "Opiferque per orbem dicor."



ACTINOMYCOSIS IN MAN AND ANIMALS.

THE investigation of actinomycosis has not kept pace with that of other granulomata, such as tuberculosis and syphilis, during the last 50 years. Dr. Leonard Colebrook, addressing the Combined Section of Comparative Medicine and Surgery at the Royal Society of Medicine on Jan. 22nd, suggested a revision of the confused nomenclature at present in use. His classification is as follows:—

I. Infections associated with granules bearing clubs. Due to: (1) *Actinomyces bovis* (Wolff Israel). (2) Mycelial organisms distinct from *Actinomyces bovis*. (3) Actinobacillus of Lignière and Spitz. (4) Staphylococcus. (5) *Bacillus pyogenes* (possibly a causative organism).

II. Infections by mycelial organisms, showing no granules, or no granules with clubs. (6) Due to unclassified organisms (streptothrix).

Dr. Colebrook suggests the term "actinophytosis" to cover the whole of Group I., but Mr. T. J. Bosworth, before speaking of actinomycosis in animals, deprecated the use of the term in veterinary practice as suggesting a connexion between several quite distinct conditions. He used "actinomycosis" and "actinobacillosis" as separate terms, and included all other lesions of a similar nature under the heading of "botryomycosis," irrespective of club-formation in the granules. Actinomycosis, due to *Actinomyces bovis*, causes lesions of the jaw in animals, and is rare elsewhere. It does not involve the lymph glands, though these often become enlarged owing to chronic adenitis. Actinobacillosis, due to the bacillus of Lignière and Spitz, is more common than actinomycosis in animals, and usually affects the head and neck; more rarely the skin, lungs, liver, and intestine. This condition involves the lymph glands. "Botryomycosis" usually affects the udder only in cattle, and the differential diagnosis is from tuberculosis; in swine it affects the passed along the lumen of the laryngoscope in order to obtain material for culture.

---

[1] Proc. Roy. Soc. Med. (Hist. Sect.), 1929, xxiii., 11.

If suction is to be applied an aspirating tube is passed until its tip lies about an inch beyond the vocal cords. These suction tubes are of a special make and cannot be obtained from the ordinary instrument-maker. They are plain brass tubes 14½ inches long and, about six inches from the proximal end, they are bent at an angle of 140 degrees so that the surgeon's hand does not obstruct his view. The proximal part is widened to make a handle, on which is provided a nipple for connexion with the rubber suction tube. The tip of the tube is carefully bevelled off. Like the laryngoscopes, the tubes are unplated. They are used in three sizes: (1) small; internal diameter of main stem 3 mm.; external diameter, 5 mm., internal diameter of tip 2 mm., and external diameter 4 mm.; (2) medium; external diameter of main stem 6 mm.. and of tip 5 mm., internal diameter of tip 3 mm.; (3) large; external diameter of main stem 7 mm., and of tip 6 mm., internal diameter of tip 4 mm. Dr. J. D. Smith, the director of hospitals at the Willard Parker, prefers a special type of tube which resembles a male catheter; it has a blind end, with a hole measuring 10 by 3 mm., placed 12 mm. from the tip. The portable suction apparatus is run off the hospital current and two sets should be available in case of emergency.

Between the applications of the suction tube, water is drawn through it, so that its lumen is kept clear and the surgeon can see how much membrane has been removed. Finally, the larynx is inspected, and if there is a raw, oozing surface it is swabbed with adrenalin.

A supply of sterile laryngeal swabs is kept in readiness for making direct cultures and for applying adrenalin. The swabs are inserted by means of clamped artery forceps. To prevent the wool becoming detached in the larynx the pledget is fixed to the swab stick by collodion.

The nose and mouth of the operator are protected by a mask and his eyes by plain glass spectacles. The whole operation only takes a few minutes and should not cause the patient more than a little discomfort. No anæsthetic is necessary. As soon as the procedure is finished the patient is sent back to bed and given diphtheria antitoxin.

Advantages of Aspiration.

The first advantage claimed for this method is the accurate diagnosis which can be made after direct inspection and direct culture. The diagnosis also aids prognosis; the workers at the Willard Parker Hospital believe that laryngeal diphtheria has a better prognosis than other forms of acute laryngitis with obstruction. Secondly, the direct removal of the membrane by suction restores the air-way which has been partly or completely blocked by it. At the stage at which patients usually come to hospital the membrane is detached easily and there is little œdema and no hæmorrhage. Earlier in the illness there is usually a good deal of œdema and the membrane is very adherent; if the symptoms are not urgent expectant treatment is adopted. Later in the illness, when relief is urgently needed, direct intubation is performed, but suction, its supporters claim, often obviates the necessity for intubation, and in any case diminishes the incidence of broncho-pneumonia.

Dr. Joe's report gives the tables which he was able to compile from the records of the Willard Parker, Kingston-avenue, and Queensboro Hospitals. These institutions have 864 beds between them. Unfortunately the figures only date from 1927. At the Willard Parker Hospital there was a progressive decrease in the death-rate of intubated cases of diphtheria from 54 per cent. in 1922 to 25 per cent. in 1926, followed by a considerable drop—to 16·6 per cent.—in 1927. Making allowance for the reduced severity of diphtheria from 1922 to 1926, Dr. Joe thinks that at least part of the decrease was fairly attributable to the introduction of the suction method. Since 1927 the percentage of mortality has shown an increase to 28·5 in 1928, and 37·5 in the first nine months of 1929. Dr. Joe points out that these figures are not quite fair to the suction method, as they only represent the percentage of deaths after intubation, and the suction method has been steadily reducing the number of cases which require intubation. Moreover, the increasing accuracy of diagnosis may also be related to the increased death-rate. The figures do not supply an answer to the question of how far the new method has reduced the need for intubation. Before 1927 laryngeal diphtheria was not separated from the other cases of diphtheria, but there has been a steady fall in the percentage of all cases of diphtheria which required intubation. Since Dr. Joe's return to England he has received from Dr. Smith the information that in the year 1918–19 the Willard Parker Hospital admitted 697 cases of croup, and that of these 286, or 41 per cent., required intubation, while the mortality after intubation was 41·6 per cent. In 1928, 407 cases of laryngeal diphtheria were admitted; of these, 77, or 4 per cent., only were intubated.

Cases Seen Personally by Dr. Joe.

Of the 11 cases seen by Dr. Joe while he was in New York six were finally diagnosed as laryngeal diphtheria. Two of them were not treated by suction as there was no membrane in the larynx; two more had a moderate amount of obstruction, but Dr. Joe remarks that he would not have considered them serious enough for operative interference, while the remaining two were very severe, and he would have performed tracheotomy or intubation on them at once. The two milder cases gradually recovered without any dramatic alleviation of their symptoms, but the two severe cases demonstrated the value of the aspiration method very forcibly, and Dr. Joe gives the details of them.

The first was a boy, aged 5, who had extensive membrane on the fauces, and was exhausted and livid, with a rapid, thready, pulse and marked recession of the soft parts. Laryngoscopy revealed a good deal of membrane on the epiglottis and larynx and flapping about in the trachea. On the first application of suction, several pieces of membrane were brought out, and the second application removed a complete cast of the trachea and proximal half-inch of both bronchi. All obstructive symptoms disappeared, the patient's colour and pulse improved, and he was asleep when carried out of the theatre. Symptoms of moderate obstruction appeared again 22 hours later; aspiration was repeated, several more fragments removed, the symptoms again completely relieved, and recovery was uneventful.

Dr. Joe's conclusion is that the method is safe and involves, in the hands of a skilled operator, little more than temporary discomfort, and certainly much less shock than tracheotomy. He sees no reason why aspiration should not be employed as an adjunct to tracheotomy as well as to intubation.

WESTMINSTER HOSPITAL.

OPENING OF THE RADIUM TREATMENT ANNEXE.

THE Radium Annexe, which was formerly opened by Viscount Lee of Fareham last Wednesday, Jan. 29th, at 66, Fitzjohn's-avenue, London, N.W., owes its origin to the fact that while public recognition of the value of radium was still lacking two munificent gifts, one from Mr. Austin Taylor, later chairman of the hospital, the other from the Prudential Assurance Company, enabled progress to be made in 1925 with the radium treatment of certain types of cancer. The house committee of the hospital desiring, in 1927, to make the treatment available to all who might benefit from it, an appeal for funds realised nearly £25,000, which was immediately used for the purchase of radium, and by the end of 1928 the hospital possessed three-quarters of a gramme in the form of needles and one gramme which could be used as a unit for the treatment of forms of cancer which had hitherto been regarded as beyond surgery. The problem of accommodation for the increasing numbers of patients then arose, and it became clear that further progress depended upon the coöperative efforts of teams of specialists and surgeons, pathologists, radiologists, physicists, and technical engineers, all working together under one roof. To meet this twofold need it was resolved to establish a separate Annexe, and this was partially made possible by two anonymous donations of £4000 and £5000 each. A building in Fitzjohn's-avenue, Hampstead, was purchased, and plans were made for its adaptation and equipment. Funds were quickly forthcoming, and there is a list of 845 founders, headed by the name of H.R.H. the Prince of Wales. The National Radium Commission recently decided to entrust to the hospital four grammes of radium, on loan from the Union Minière Belge, for use in a single unit. This "bomb" has now been purchased by the Radium Trust and will be in use day and night at the Annexe.

Accommodation.

In the *basement* is (1) a pathological laboratory, in which portions of growth are microscopically examined to determine their original nature and the effects upon them of radiation; examinations of blood are also conducted to serve as a measure of the amount of radiation received by a patient—experimental work on the genesis of cancer is being undertaken; (2) a biochemical laboratory: determination of a patient's tolerance to sugar is here conducted as a measure of his or her reaction to irradiation—an investigation into the cause of cancer from the point of view of the action of fat-soluble agencies is also being carried out; and (3) a physics laboratory: here research is being conducted with a view to the determination of the best means of utilising the supply of radium both in the "bomb" and in the form of needles in order to obtain the maximum destructive power on a growth without injury to the normal surrounding tissues. Here is also (4) the emanation room, containing apparatus for the preparation of radium "seeds," and (5) the deep X ray set room, containing the apparatus necessary for generating at 230,000 volts the X rays used in the deep therapy departments.

On the *ground floor* is (1) the radium bomb room, lined with barium for the protection of workers in adjacent rooms; by means of specially constructed apparatus its rays are directed on two patients simultaneously; (2) the deep X ray therapy department for the irradiation of deep-seated malignant growths, to be compared with irradiation by means of the bomb; (3) the X ray diagnostic department, chiefly used for locating and localising tumours preparatory to their treatment; (4) the dark room, the walls of which, in accordance with modern practice, are painted cream and all work is done by reflected light. On this floor is the male ward with six beds and the female ward with four beds for those unable to contribute, as well as the medical officers' consulting room.

On the *first floor* are seven rooms for the accommodation of paying patients, one three-bedded and one two-bedded ward for the accommodation of those able to contribute not more than £3 3*s*. to £4 4*s*. per week (no medical fees being charged); also the operating theatre, sterilising room, and anæsthetic room.

On the *second floor* is accommodation for two sisters, ten nurses, and four maids. The nurses have their dining and sitting rooms on the ground floor.

Opening Ceremony.

In asking Lord Lee to open the Annexe, the chairman of the hospital, Mr. K. A. Wolfe Barry, said that although separated geographically, the Annexe would be as much a part of the hospital as any ward or special department of the main building. Their surgical staff, after visiting those centres on the Continent where, radium treatment of cancer was being practised, had persuaded the governors of the hospital to take their courage in both hands and to establish a separate department where, alongside treatment by all radium methods, research might be carried out not only into the cause of the disease but also, what was as important, into improved methods of technique. The building, with 22 beds for patients, special rooms for a radium bomb and deep X ray therapy, a theatre, accommodation for the nursing and domestic staff, and all the necessary laboratories for routine and research purposes, was being opened free from debt, although they were not without anxiety for maintenance and running cost. If they had the means they would house the nursing staff in an adjacent building and give up the top floor to further accommodation for patients. This was, he added, the first time that such a mass of radium as four grammes had been used as one unit in this country, and the hospital was proud to be entrusted with it.

Administrative Committee.

The committee which has been selected to administer the Annexe consists of eight members, two of them being surgeons to the hospital—namely, Mr. R. H. Thorpe (chairman), Mr. H. M. Clowes (vice-chairman), Mr. Wolfe Barry and Lieut.-Colonel H. C. Bulkeley (ex officio), Mr. William Turner, F.R.C.S., Mr. E. Rock Carling, F.R.C.S., Mr. J. D. C. Couper, and Major S. R. Stott.

NOTES FROM INDIA.

(FROM OUR OWN CORRESPONDENT.)

Medical Research.

THE recommendation of Sir Walter Fletcher's Committee that Dehra Dun should be selected for the Imperial Research Institute seems now to have been definitely adopted, in spite of the local claims of the presidency towns. There has been acrimonious discussion in the Legislative Assembly and elsewhere, and no doubt there would be advantages in the vast amount of clinical material which the hospitals in the large cities are in the position to supply, but the existing research laboratories in Calcutta, Bombay, and Madras will still have their opportunities, and the recently issued report for 1928 of the Haffkine Institute in Bombay furnishes a good example of the variety of work with which they have to deal. During the year under report the Institute has been investigating sprue, various forms of anæmia (particularly in relation to pregnancy), and tuberculosis. An inquiry has been conducted into the possibility of improving the mode of preparation of plague vaccine, with which Bombay supplies the whole of India, and the examination of indigenous drugs, which has now been going on for some years has been continued, as well as an inquiry into the factors which give rise to earth-eating. The plague investigation has not led to any modification in the process of manufacture, but as so often happens in such cases a result has been indirectly arrived at which will prove very useful. The discovery that blood agar is the best medium for the growth of the plague bacillus has facilitated the detection of contaminating organisms in the vaccine. Anæmia is very prevalent in Bombay, and the researches have shown that the forms associated with sprue and pregnancy bear a close resemblance to pernicious anæmia. It is thought that the anæmia of pregnancy is not a distinct entity, as has sometimes been suggested. The Institute also serves as a centre for antirabic treatment. The report closes with an expression of regret that the Institute is still cramped for funds, and that no further advance has been made in the direction of establishing a school of tropical medicine in connexion with it.

Cholera in a Hill Tract.

Evidences of progress in medical work are to be seen just now in the Punjab, where a large number of fresh rural dispensaries have been established during the last few years, and the public health report of the province for 1928 is full of interest. The year was an exceptionally healthy one, the death-rate being 24·72 per mille, as against a birth-rate of 40·30—

passed along the lumen of the laryngoscope in order to obtain material for culture.

If suction is to be applied an aspirating tube is passed until its tip lies about an inch beyond the vocal cords. These suction tubes are of a special make and cannot be obtained from the ordinary instrument-maker. They are plain brass tubes 14½ inches long and, about six inches from the proximal end, they are bent at an angle of 140 degrees so that the surgeon's hand does not obstruct his view. The proximal part is widened to make a handle, on which is provided a nipple for connexion with the rubber suction tube. The tip of the tube is carefully bevelled off. Like the laryngoscopes, the tubes are unplated. They are used in three sizes: (1) small; internal diameter of main stem 3 mm.; external diameter, 5 mm., internal diameter of tip 2 mm., and external diameter 4 mm.; (2) medium; external diameter of main stem 6 mm., and of tip 5 mm., internal diameter of tip 3 mm.; (3) large; external diameter of main stem 7 mm., and of tip 6 mm., internal diameter tip 4 mm. Dr. J. D. Smith, the director of hospitals at the Willard Parker, prefers a special type of tube which resembles a male catheter; it has a blind end, with a hole measuring 10 by 3 mm., placed 12 mm. from the tip. The portable suction apparatus is run off the hospital current and two sets should be available in case of emergency.

Between the applications of the suction tube, water is drawn through it, so that its lumen is kept clear and the surgeon can see how much membrane has been removed. Finally, the larynx is inspected, and if there is a raw, oozing surface it is swabbed with adrenalin.

A supply of sterile laryngeal swabs is kept in readiness for making direct cultures and for applying adrenalin. The swabs are inserted by means of clamped artery forceps. To prevent the wool becoming detached in the larynx the pledget is fixed to the swab stick by collodion.

The nose and mouth of the operator are protected by a mask and his eyes by plain glass spectacles. The whole operation only takes a few minutes and should not cause the patient more than a little discomfort. No anæsthetic is necessary. As soon as the procedure is finished the patient is sent back to bed and given diphtheria antitoxin.

Advantages of Aspiration.

The first advantage claimed for this method is the accurate diagnosis which can be made after direct inspection and direct culture. The diagnosis also aids prognosis; the workers at the Willard Parker Hospital believe that laryngeal diphtheria has a better prognosis than other forms of acute laryngitis with obstruction. Secondly, the direct removal of the membrane by suction restores the air-way which has been partly or completely blocked by it. At the stage at which patients usually come to hospital the membrane is detached easily and there is little œdema and no hæmorrhage. Earlier in the illness there is usually a good deal of œdema and the membrane is very adherent; if the symptoms are not urgent expectant treatment is adopted. Later in the illness, when relief is urgently needed, direct intubation is performed, but suction, its supporters claim, often obviates the necessity for intubation, and in any case diminishes the incidence of broncho-pneumonia.

Dr. Joe's report gives the tables which he was able to compile from the records of the Willard Parker, Kingston-avenue, and Queensboro Hospitals. These institutions have 864 beds between them. Unfortunately the figures only date from 1927. At the Willard Parker Hospital there was a progressive decrease in the death-rate of intubated cases of diphtheria from 54 per cent. in 1922 to 25 per cent. in 1926, followed by a considerable drop—to 16·6 per cent.—in 1927. Making allowance for the reduced severity of diphtheria from 1922 to 1926, Dr. Joe thinks that at least part of the decrease was fairly attributable to the introduction of the suction method. Since 1927 the percentage of mortality has shown an increase to 28·5 in 1928, and 37·5 in the first nine months of 1929. Dr. Joe points out that these figures are not quite fair to the suction method, as they only represent the percentage of deaths after intubation, and the suction method has been steadily reducing the number of cases which require intubation. Moreover, the increasing accuracy of diagnosis may also be related to the increased death-rate. The figures do not supply an answer to the question of how far the new method has reduced the need for intubation. Before 1927 laryngeal diphtheria was not separated from the other cases of diphtheria, but there has been a steady fall in the percentage of all cases of diphtheria which required intubation. Since Dr. Joe's return to England he has received from Dr. Smith the information that in the year 1918–19 the Willard Parker Hospital admitted 697 cases of croup, and that of these 286, or 41 per cent., required intubation, while the mortality after intubation was 41·6 per cent. In 1928, 407 cases of laryngeal diphtheria were admitted; of these, 77, or 4 per cent., only were intubated.

Cases Seen Personally by Dr. Joe.

Of the 11 cases seen by Dr. Joe while he was in New York six were finally diagnosed as laryngeal diphtheria. Two of them were not treated by suction as there was no membrane in the larynx; two more had a moderate amount of obstruction, but Dr. Joe remarks that he would not have considered them serious enough for operative interference, while the remaining two were very severe, and he would have performed tracheotomy or intubation on them at once. The two milder cases gradually recovered without any dramatic alleviation of their symptoms, but the two severe cases demonstrated the value of the aspiration method very forcibly, and Dr. Joe gives the details of them.

The first was a boy, aged 5, who had extensive membrane on the fauces, and was exhausted and livid, with a rapid, thready, pulse and marked recession of the soft parts. Laryngoscopy revealed a good deal of membrane on the epiglottis and larynx and flapping about in the trachea. On the first application of suction, several pieces of membrane were brought out, and the second application removed a complete cast of the trachea and proximal half-inch of both bronchi. All obstructive symptoms disappeared, the patient's colour and pulse improved, and he was asleep when carried out of the theatre. Symptoms of moderate obstruction appeared again 22 hours later; aspiration was repeated, several more fragments removed, the symptoms again completely relieved, and recovery was uneventful.

Dr. Joe's conclusion is that the method is safe and involves, in the hands of a skilled operator, little more than temporary discomfort, and certainly much less shock than tracheotomy. He sees no reason why aspiration should not be employed as an adjunct to tracheotomy as well as to intubation.

WESTMINSTER HOSPITAL.

OPENING OF THE RADIUM TREATMENT ANNEXE.

THE Radium Annexe, which was formerly opened by Viscount Lee of Fareham last Wednesday, Jan. 29th, at 66, Fitzjohn's-avenue, London, N.W., owes its origin to the fact that while public recognition of the value of radium was still lacking two munificent gifts, one from Mr. Austin Taylor, later chairman of the hospital, the other from the Prudential Assurance Company, enabled progress to be made in 1925 with the radium treatment of certain types of cancer. The house committee of the hospital desiring, in 1927, to make the treatment available to all who might benefit from it, an appeal for funds realised nearly £25,000, which was immediately used for the purchase of radium, and by the end of 1928 the hospital possessed three-quarters of a gramme in the form of needles and one gramme which could be used as a unit for the treatment of forms of cancer which had hitherto been regarded as beyond surgery. The problem of accommodation for the increasing numbers of patients then arose, and see that the advice then given is carried out. Malnutrition is more often the result of improper diet than of insufficient food. He goes on to enumerate some of the serious defects that may be present unnoticed in a child unless he is subjected to personal inspection. Among these are defective teeth, diseased tonsils, chronic adenitis, and even active tuberculosis. Dr. Harbison's clearly written articles should help to make his work in county Kildare successful.

Death of Dr. Thomas Dowse.

One of the most highly respected practitioners in the south-east of Ireland, Dr. Thomas J. Dowse, of Wexford, has recently died. He obtained his medical degrees from Dublin University in 1881, and spent his professional life in Wexford, where he was physician to the County Hospital. He was a man of high professional skill, punctilious in his attentions to his patients, and generous and courteous in his treatment of the poor. He was held in universal esteem in Wexford by all classes of the community, as well as by his professional brethren. He came of a family which has given many members to medicine, while others have reached high offices in the Church.

SCOTLAND.

(FROM OUR OWN CORRESPONDENT.)

The Universities in Public Administration.

IN a recent address to the Institute of Public Administration, Dr. T. J. Mackie, professor of bacteriology in the University of Edinburgh, pleaded for a more extended use of Universities and University staffs in the health and research work of the public authorities. Problems, he said, were continually confronting our governing authorities, central and local, in which expert assistance was required beyond the scope of their own permanent officials. The names of University professors were often to be seen among the members of Royal Commissions and Government Committees, and investigations of public importance were sometimes referred to University experts; but he wondered whether the full possibilities of the Universities in this respect were perfectly appreciated, and whether the knowledge of University workers was utilised sufficiently in the common good. In the Universities the central and local governments could find a wide choice of advisors, consultants, and investigators for the very various problems which every day beset them.

Prof. Mackie also discussed an urgent question of the moment—namely, the relation of the new hospital organisation to the University medical schools—and suggested that it might be to the advantage of certain local authorities to enlist medical school coöperation in the medical management of their new municipal hospitals. In recent years, the medical schools had recognised that remedial measures and prophylaxis through research must go hand in hand. Some of them had attempted to institute full-time professorships in the main clinical subjects, so that the occupant of the chair might devote himself entirely to hospital work, teaching, and research. Was it not possible that in University centres the hospitals of the future might be most effectively staffed—in the interests of the public, of medical education, and of research—by a whole-time medical school personnel, and so become still greater centres of progressive medicine—in short, University hospitals?

Prof. Mackie's paper will, no doubt, be published in full. He strikes the same note as many of the younger men in the medical profession who look forward to a closer integration of teaching, research, and administration, as against the policy hitherto favoured by the voluntary bodies of strict independence and reservation of offices for the men in so-called "consulting" practice. Views are far from unanimous, and much is to be said from each side; but we have reached the moment for a radical discussion of the possibilities of "coöperation," if only to meet the rising demand for more treatment and more investigation of disease on the extended scale open only to well-equipped institutions.

INFECTIOUS DISEASE IN ENGLAND AND WALES DURING THE WEEK ENDED JAN. 18TH, 1930.

Notifications.—The following cases of infectious disease were notified during the week:—Small-pox, 414 (last week 335); scarlet fever, 2068; diphtheria, 1819; enteric fever, 44; pneumonia, 1204; puerperal fever, 72; puerperal pyrexia, 119; cerebro-spinal fever, 8; acute poliomyelitis, 5; encephalitis lethargica, 19; continued fever, 1; dysentery, 7; ophthalmia neonatorum, 96. No case of cholera, plague, or typhus fever was notified during the week.

Fresh small-pox cases, while fewer in London than in the previous week, were more numerous in some other counties and were more widely distributed. Derby reported 1 (R.D. Chesterfield): Essex, 54 (East Ham, 1; West Ham, 36; Walthamstow, 11); Hertford, 1 (East Barnet Valley); Leicester, 68 (42 in the County Borough); Middlesex, 4 (Tottenham, 3; Wood Green, 1); Northampton, 1 (Rothwell); Peterborough, 1 (Borough); Sussex East, 6 (Eastbourne); Warwick, 3 (Coventry, 1; Nuneaton, 2); Yorkshire West Riding, 70 (Dewsbury, 3; Halifax, 4; Huddersfield, 13; Leeds, 31; and in urban districts, Batley, 9; Birstal, 5; Rothwell, 20; Spenborough, 9.

The number of cases in the Infectious Hospitals of the Metropolitan Asylums Board on Jan. 21st–22nd was as follows:—Small-pox, 528 under treatment, 18 under observation (last week 503 and 33 respectively); scarlet fever, 2482; diphtheria, 2682; enteric fever, 23; measles, 917; whooping-cough, 124; puerperal fever, 30 (plus 10 babies); encephalitis lethargica, 119; poliomyelitis, 2; "other diseases," 16. At St. Margaret's Hospital there were 15 babies (plus 5 mothers) with ophthalmia neonatorum.

Deaths.—In the aggregate of great towns including London there was 1 death from small-pox, 3 (1) from enteric fever, 60 (22) from measles, 10 (3) from scarlet fever, 18 (1) from whooping-cough, 62 (12) from diphtheria, 59 (17) from diarrhœa and enteritis under two years, and 67 (15) from influenza. The figures in parentheses are those for London itself.

Small-pox was mentioned as a cause of death in a case assigned to the Metropolitan Borough of Shoreditch. (The returns for December, just received, include a fatal case provisionally classed to small-pox at Rawmarsh U.D. Yorks W.R.) The two cases of enteric fever outside London were both reported from Manchester. Six fatal cases of measles were reported from Wigan, 5 from West Ham, and 3 from Manchester. Leeds reported 3 fatal cases of scarlet fever, Newcastle-on-Tyne 3 of whooping-cough. Fatal cases of diphtheria were widely distributed: Ipswich and Liverpool each 4, Southampton, Bristol, Birmingham, and Hull each 3. Liverpool had 7 deaths to report from diarrhœa, Manchester and Newcastle each 4. The highest figures for influenzal deaths are reported from Birmingham and Manchester each 6.

The number of stillbirths notified during the week was 311 (corresponding to a rate of 47 per 1000 births), including 55 in London.

Fatal Case of Small-pox.—The death mentioned above was that of a boy 10 years of age, unvaccinated, who became ill with headache and sickness on Dec. 29th. Spots first appeared on Jan. 4th or 5th. Dr. Maitland Radford, medical officer of health for Shoreditch, tells us he was asked to see the boy on Jan. 7th, when he found a typical small-pox (mild type) eruption, the boy seeming much more ill than is usual with this type of case. The boy died on Jan. 12th in the Joyce Green Hospital, the cause of death on the certificate being stated: (*a*) encephalomyelitis, (*b*) small-pox.

BOLINGBROKE HOSPITAL.—This institution, at Wandsworth Common, last year treated 2252 in-patients and 13,022 new out-patients. The average residence in-patients was 15·8 days.

"Audi alteram partem."

EARLY DISCHARGE OF SCARLET FEVER CONVALESCENTS.

To the Editor of THE LANCET.

SIR,—In your interesting survey of the Reports of Medical Officers of Health for 1928 you observe, under the heading of Infectious Diseases, that "the use of antitoxin for *scarlet fever* is reported upon favourably, and several isolation hospitals claim to be discharging scarlet fever cases after 28 days without harmful results." The suggestion is that the use of the serum has enabled the discharge of patients at the end of so short a period. May I be permitted to point out that 29 years ago at the Eastern Hospital, Homerton, I began the practice of discharging all mild and uncomplicated cases of scarlet fever at the end of four weeks (see Annual Report of the Metropolitan Asylums Board for the year 1903, page 208 and page 177)? And I continued it till I retired in 1926.

Nor was I alone in this practice. The late Dr. J. B. Curgenven had forestalled me in 1890, and he was followed by the late Dr. Robert Milne. They both attributed the safety of the discharge of scarlet fever patients on an earlier day than was customary to the use, chiefly, of eucalyptus oil. They were both right in their practice but wrong in their explanation of its safety. Most of us were in those days under the influence of the fetish of the supposed infectiousness of the peeling cuticle, and were too timid to move against custom. I should not be surprised to hear that it was safe to discharge some scarlet fever patients before the end of the fourth week, quite apart from the use of serum. But the use of serum, by hastening recovery and preventing complications, should lead to the early discharge of a larger number of scarlet fever patients than heretofore.

I am, Sir, yours faithfully,
E. W. GOODALL.

Hemingford Abbots, Hunts, Jan. 26th, 1930.

CHEST COMPLICATIONS AFTER OPERATION.

To the Editor of THE LANCET.

SIR,—In Dr. C. J. Fuller's paper and a leading article in your issue of Jan. 18th the incidence of post-operative chest complications was discussed. Diaphragmatic inertia was shown to be one of the causative factors and, in order to counteract this, respiratory exercises were prescribed, but the practical results from these fell far short of anticipation. As regards these exercises, full expansion either of both lungs simultaneously or of single lungs alternatively was attempted; diaphragmatic movement at the culmination of a thoracic breath was aimed at. The fact that there is an alternative method which is an extremely simple one to teach has led me to presume on your valuable space.

Sir Arthur Keith (1909) showed that the upper lobes are chiefly expanded by the upper ribs. He analysed the diaphragm into the crura and the sterno-costal portion, the former acting chiefly through the roots and on the apices of the lungs. Sir Charlton Briscoe (1920–27) expanded this conception and utilised contraction of the dome of the diaphragm to aerate the lower lobes of the lungs. As regards the interplay of the alternative respiratory muscles he considered that, according to Blix's law, "stretch" was the determinant. Lady Briscoe (1928) in some beautiful laboratory experiments demonstrated selective activity of the dome and crura of cats by alteration of position of the spinal column, the criterion being that extension of the spine readjusted the relative "stretches" of the crura and dome in favour of the former.

Prof. Wood Jones (1913) showed that anchorage of the alternative respiratory muscles in accordance with posture determined the breathing mechanism that predominated in various animals. Utilising the above information I have been using selective breathing movements, when re-educating the abdominal wall, and more recently, when dealing with bed-patients convalescing from abdominal operations. From the point of view of treatment the abdominal wall and diaphragm are a convenient pair (prime-mover and antagonist); selective breathing movements fulfill the desiderata: "little and often," relaxation of the antagonist, selection of the "true function" (Mackenzie) and a suitable task for a damaged muscle, all of which are laid down by Dr. J. B. Mennell in connexion with muscle re-education. The forcible exercises given to Dr. Fuller's patients contravened the principle that "no enfeebled muscle should ever be stretched" (Mennell).

When re-educating the diaphragm, an initial expiratory movement should be made by a slow coördinated contraction of the abdominal wall; this anchors the periphery of the dome of the diaphragm and gives the muscle adequate "stretch." Coördination of the abdominal wall and avoidance of thoracic movement come easily, if the patient lays his hands on the chest and on the abdomen, both on the binder and free areas. These movements, if sufficiently controlled, will be found painless and are popular with patients, as they often help flatulence.

I am, Sir, yours faithfully,
J. K. McCONNEL.

Clifton Hill, St. John's Wood, Jan. 23rd, 1930.

MUSCULAR MOVEMENTS OF THE COLON.

To the Editor of THE LANCET.

SIR,—In his informative article on radiography of the colon (THE LANCET, Dec. 28th, 1929, p. 1377), Dr. Barclay tells us that movements corresponding to ordinary peristalsis are not seen on the fluoroscopic screen, but only mass movements occurring a few times per day. It is difficult to reconcile this interesting statement with clinical experience, authoritatively rendered as it is by an experienced radiographer. For example, frequent colonic movements are experienced by everyone in slight intestinal disturbances, following the taking of a laxative, in the dispersion of bowel flatulence, and so forth. Are we to understand that these movements are all of the mass movement type? Clinically they appear to be ordinary peristalsis. One thinks, too, of visible peristalsis in chronic intestinal obstruction. Perhaps Dr. Barclay would be good enough to explain the point. I am, Sir, yours faithfully,
L. J. GREEN.

High-road, S. Tottenham, N., Jan. 19th, 1930.

COMPULSORY TREATMENT OF VENEREAL DISEASE.

To the Editor of THE LANCET.

SIR,—Any opinion advanced by Dr. Sequeira deserves careful consideration, and his letter in your issue of Jan. 18th is very much to the point. Two years ago I contributed [1] to a correspondence in THE LANCET that took place regarding the venereal campaign and referred to the Edinburgh Bill, when I expressed the opinion that while a great teaching centre and medical school like Edinburgh, to which preventive medicine owes so much, might safely be permitted to carry out a local experiment in prevention by compulsory treatment, I personally, in view of the wide divergence of medical opinion as to what constitutes effective treatment, did not consider legislation enforcing treatment practical or desirable *except for a short minimal period of three months*, which should be sufficient in the great majority of, but of course not in all, cases to render the patient non-contagious.

---

[1] THE LANCET, 1928, i., 883.

Such a minimal course of compulsory treatment for syphilis or gonorrhœa would not, I gather, offend Dr. Sequeira and those who think with him, and might be accepted as a compromise by the advocates of compulsory treatment. Three months compulsory treatment for syphilis and three months compulsory treatment or attendance for observation for gonorrhœa (for most cases of the latter are cured in less than three months) would do much good and little, if any, harm.

I am, Sir, yours faithfully,

H. WANSEY BAYLY.

Harley-street, W., Jan. 22nd, 1930.

MENTAL TREATMENT BILL.

To the Editor of THE LANCET.

SIR,—In your leading article (Dec. 7th, 1929), commenting on Clause 2 (1) of Lord Russell's Bill, you say:—

> If a person with mental disturbance voluntarily asks for treatment in a hospital or home, why should he, more than any other invalid, have to be notified to the Board of Control? . . . It is obvious that those in charge of such patients, let alone the patients themselves and their relatives, will object to compulsory notification. . . . We trust that obligation to notify all voluntary mental patients will be withdrawn, and discretion left to the medical man responsible for the treatment of the patient."

It is evidently for the good of the community that cases of slight instability which cannot be proved to be dangerous or unfit to be at large should be treated on a voluntary footing in places without detention, and that everything should be done to make it easy for them to come to a hospital at an early stage, and *of their own accord;* whereas if they think that they are placing themselves under Lunacy control they are likely to hesitate, and thus the chance of a speedy recovery may be delayed. It is natural also that not a few members of the medical profession are averse to having their uncertified patients compulsorily notified to the Board of Control.

As regards transient cases of high temperature with delirium (e.g., puerperal, pneumonic, influenzal) it is very undesirable to treat such cases in asylums because there is there no qualified nursing staff competent to take charge of patients in such peril of their lives. Delirium subsides in the course of a few weeks, when the patient becomes again normal. The natural way to keep such cases safe from stigma is to treat them as *hospital cases* in homes or hospitals appropriately staffed, and apart from lunacy administration.

If public asylums wish to open their doors to voluntary boarders a short Bill could be brought in for the purpose (as in the case of Maudsley and Dartford). In places where patients know they are *not detained*, the risk of ill-treatment is minimised—as also is the necessity for inspection. It is hoped that the Bill may be amended in respect of Clauses 1–5.

I am, Sir, yours faithfully,

S. E. WHITE, M.B.

Strone-road, Manor Park, E., Jan. 28th, 1930.

MEDICAL FOUNDATIONS.

To the Editor of THE LANCET.

SIR,—I agree with all that Dr. Henry Robinson says. In a letter (entitled Thoughtful Gratitude), from myself, which you inserted last year, I pointed out that when medical men or their families are attended or prescribed for by a colleague, it would be a kindly and useful act if they sent to one of the medical foundations a cheque for a small amount. When one remembers how many medical men find it difficult in these days to save, and how often the widows of medical men are crushed down with poverty and the struggle to provide for their children, it is time that others more fortunate should stretch out a helping hand. The foundations are doing a great work, but they are anxious to do far more. Unfortunately their hands are tied by want of money, and many of us who could help—at least to a small extent—from want of thought or want of feeling, pass by, like the Levite, on the other side, and leave many unfortunate ones to battle on with their cares and their poverty.

I am, Sir, yours faithfully,

Harrogate, Jan. 20th, 1930. JAMES G. MACASKIE.

NEPHROSIS AND NEPHRITIS.

To the Editor of THE LANCET.

SIR,—In the leading article with which you have honoured my report to the Medical Research Council on A Classification of Bright's Disease you say that the student is left in some perplexity as to why the term nephritis mitis is preferred to nephrosis for one kind of nephritis. Readers will find on pages 119 to 123 reasons for objecting to this particular application by Volhard and Fahr and by Munk of Müller's term nephrosis.—I am, Sir, yours faithfully,

DOROTHY S. RUSSELL.

Bernhard Baron Institute of Pathology, London Hospital, E., Jan. 24th, 1930.

LAENNEC AND THE BRUIT D'AIRAIN.

To the Editor of THE LANCET.

SIR,—Despite "Bobo," it would seem that "Anglo-Gallicus" is really right. The name of the Breton physician should be spelt *Laennec*, as he wrote it and as he printed it on his book-plate. It is thus spelt on his monument, and, for us, in Gee's classic work. The wrong fashion, with a diæresis over the first "e," became official, as "Bobo" hints, about eighty years ago. But the French Academy in these later years has formally recanted, and all future editions of the invaluable and pleomorphic "Larousse" will conform to what is now correct, officially and unofficially. With a reversion to correct spelling, there will doubtless come about a general reversion to the pronunciation that so many accomplished Frenchmen have always preferred to the "trisyllabic" one.

Again, both "Anglo-Gallicus" and "Gallo-Britannicus" seem to be right in insisting that, to-day, *airain* be always translated as meaning either (1) bronze, or (2) an object, such as a bell, made of bronze, unless a frankly metaphorical usage is implied. The archaic, or at any rate, Elizabethan and Jacobean use of *brass*, indiscriminately, for all copper alloys, is interesting historically, but irrelevant save as an excuse for confusion.

Gee was clearly right in saying that the *bruit d'airain* does not require a coin for its production, and in translating the expression by its exact English equivalent—"bell-sound." When Trousseau spoke of the *bruit d'airain* he surely had in mind the sound so familiar to everyone who has lived in a French village and has listened, at night from his bed, or by day from the hills, to the single "strike" of the bell in the steeple.

Dr. McLaughlin and Dr. Dix-Perkin have explained to us why it was only, *par moment*, that Laennec, when practising auscultatory percussion over a pneumothorax, heard the *tintement* that *so exactly* recalls this characteristic "sound *of the bell*." For this we should be very grateful to them.

I am, Sir, yours faithfully,

F. G. CROOKSHANK.

Wimpole-street, W., Jan. 25th, 1930.

SPINAL ANÆSTHESIA.

To the Editor of THE LANCET.

SIR,—Sir Francis Shipway pointed out in his letter last week that to sit a patient up for fear a heavy solution used to produce spinal anæsthesia should "go to the brain," is an entirely obsolete and erroneous technique. Erroneous it may be but it is not quite obsolete. I saw it practised myself in one of the capitals of Europe no longer ago than last May. It was not, however, its antiquity or its error to which I particularly wished to draw attention, but the fact that it had given origin to a certain fear, the fear of a fall of blood pressure. It seemed to me that to trace the origin of this fear would be the best way to dispel it.

Turning to the letter of Dr. Howard Jones, I do not think he distinguishes with sufficient nicety between the Pitkin method and the arguments supporting that method. He says he rejected it on theoretical grounds. I would rather put it that the theoretical grounds should be rejected but the method given a prolonged trial. Pitkin's claims are exaggerated and some of his statements are demonstrably incorrect, and the excellence of the method is obscured and brought into disrepute by such extravagance. Surely a method which may reasonably be expected to give complete muscular relaxation for one and a half hours, with a degree of safety, all things considered, at least equalling that of general anæsthesia must have a very large sphere of usefulness. Novocain is the safest spinal anæsthetic we know, the gliadin tends to keep the solution together and delays absorption, thereby diminishing toxicity and prolonging the effect, both very important points, and the alcohol makes the solution lighter. Though this quality of lightness may be of no physical importance, in the present state of opinion it has very definite psychological value.

Dr. Jones says, "Most people will agree that spinal analgesia results either from a simple nerve block across the cauda equina or in the dorsal region from root block." Certainly, but neither of these processes seems to be adequate to explain the phenomena observed in the case I described. This patient felt no pain at a time (20 minutes) during which muscular rigidity was increasing after having been completely in abeyance for 40 minutes. I therefore concluded that the path of pain to the brain was blocked. Where? Is it possible that:—1. The rigidity was due to the unblocking of the efferent half of the reflex arc alone? If so, what stimulated the muscles to action? 2. Impulses passing from the seat of operation up the afferent half were responsible for the stimulus to the muscles but conveyed no pain stimulus. Both these conceptions seemed so difficult that I ventured to suggest that the anæsthetic, some of which we knew to be in the higher dorsal region, was there blocking the spinothalamic tract. It still seems to me the most likely explanation.

One more point. Dr. Jones credits me with a theory that I am unable to identify; it seems to involve the carrying on of breathing by means of the respiratory centre in the presence of paralysed phrenics. We inject novocain into the spinal theca, the abdominal muscles are completely paralysed. If the novocain goes above the third and fourth cervical, why is not the diaphragm paralysed? I suggested that novocain paralyses receptor mechanism only; that the abdominal muscles are not really paralysed but only flaccid from the complete absence of stimuli. The phrenic centre has a constant stream of afferent impulses coming to it from the respiratory centre, hence the activity of the diaphragm. There is nothing quite analogous in the case of the abdominal muscles.

I am, Sir, yours faithfully,

Manchester, Jan. 27th, 1930. E. FALKNER HILL.

MEDICINES IN THE MASS.

To the Editor of THE LANCET.

SIR,—We who practice in industrial areas are perhaps better qualified than any to speak of the large consumption of patent medicines in this country to which you alluded in a leading article last week. One sees the shelves and window sills crammed with patent medicine bottles during one's daily rounds. Patients refer to various nostrums which they may happen to be taking irrespective of what particular medicine they may be getting from oneself as their family doctor.

The high incidence of gall-stones in this neighbourhood makes the vendor of a gall-stone "remedy" a popular figure. Any herbalist down a back street in Bradford or Leeds is apparently far more skilled to "disperse" gall-stones than "the doctor," whose training apparently quite neglected this painful but common malady. One such quack sells a remedy consisting of a bottle of oil and some powders. By taking these, all gall-stones in the patient's body speedily deliquesce and flow easily into the alimentary tract and are voided in the fæces. The patient triumphantly extracts the alleged stones from the fæces and brings them up forthwith to the surgery. One of my patients who had been suffering from renal colic and in whom a stone was afterwards shown by X rays to be lying at the lower end of the ureter, for some mysterious reason—or because I had once suggested gall-stone colic—went and spent 23*s.* for the oil and two powders, and with great glee, a day or two later, brought a number of fæcal-looking lumps in a piece of paper to the surgery. "My gall-stones," he exclaimed, breathless with excitement. Examination showed that they were formed simply by the combination of the oil and powders in the alimentary tract. Only this morning I was told of a woman suffering from no symptoms suggestive of gall-stones, who had taken the above "remedy," and had passed 350 gall-stones!

Is it not time that something was done by Parliament to put down this iniquitous traffic? So long as such a combination of ignorance and credulity exists amongst the masses of this country, so long will the quack flourish. Here in the West Riding where the depression of trade is so acute—patients are apt to remind us of it shortly before the account goes in—it is nothing less than criminal that a working man can be so easily induced to part with 23*s.* for a fictitious cure of a disease which he does not possess.

I am, Sir, yours faithfully,

Jan. 27th, 1930. M.R.C.S., L.R.C.P.

The Services.

ROYAL NAVAL MEDICAL SERVICE.

Surg. Capts. (Retd.) to be Surg. Rear Admirals (Retd.): H. J. Chater and R. W. G. Stewart.

The following appointments are notified:—Surg. Comdr. L. R. Warburton to *Victory*, for R.N. Barracks, Portsmouth; Surg. Lt. W. D. M. Sim to *Vindictive*.

ROYAL ARMY MEDICAL CORPS.

Lt.-Col. J. G. Bell, having attained the age for compulsory retirement, is placed on retd. pay.

Capt. W. O. Holst to be Maj.

E. F. Hunt is granted a temp. commn. in the rank of Lt.

ROYAL ARMY DENTAL CORPS.

Capt. A. A. McMullan to be Maj.

TERRITORIAL ARMY.

Capt. R. B. Rutherford to be Maj.

ROYAL AIR FORCE.

Flight Lt. F. T. Boucher resigns his commission on appointment to a commission in the Royal Army Medical Corps.

Obituary.

PHILIP BOOBBYER, M.D., M.S. DURH.

WE noted last week the death of Dr. Boobbyer within a few days of his retirement from the medical officership of Nottingham, a post which he had filled for forty years. His death occurred suddenly on Jan. 21st, in his seventy-third year.

DR. BOOBBYER.

[Photograph by Lafayette.

Philip Boobbyer was the son of Joseph Hurst Boobbyer and came of Huguenot stock, a fact which may have some relation to the almost religious fervour with which he put through large schemes of social welfare. He was educated at Brighton College with a view to becoming an engineer, but after two years of machine-drawing he discovered his bent was for medicine and went to King's College, London, qualifying in 1881 and taking the higher degrees of the University of Durham some years later. After qualifying he was resident at King's College Hospital and demonstrated anatomy at Newcastle before succeeding Dr. B. A. Whitelegge as medical officer of health for the borough of Nottingham. He was then only 31 years of age and had already for some years been health officer to the Basford Rural Sanitary Authority. The development of health services at Nottingham is practically the record of Boobbyer's forty years term of office. One of its chief landmarks is the abolition of the pail-closet system in the city and the coincident disappearance of typhoid; had Boobbyer had his way the change would have been complete long before, but even a convinced medical officer has to convert his lay colleagues, and the conversion cost the city over half a million. Open-air methods were his great hobby, whether it was a question of letting air into the infant school, the sanatorium, or public places of entertainment. The cottage hospital and school for tuberculous children at Thurgarton was one practical outcome of his enthusiasm, but it was not propaganda or stunts that filled up the bulk of his time for he was fully occupied with the routine work of a sanitary department, the personnel of which increased during his tenure from 30 or 40 to 220. He was also examiner in public health for the universities of Birmingham and Sheffield and the Royal Sanitary Institute. Apart from his annual reports his contributions to medical literature were slight; they included a special report to the Home Office on the health of lace dressers, and articles on the open-air treatment of small-pox and other acute specific diseases. But to understand the principles which infused his work it is only necessary to read the report presented last year to the Nottingham public health authority, in which he sketched the development of local public health measures during the preceding thirteen years.

A colleague in the public health services writes: "I met Boobbyer at the Plymouth Congress in the summer of 1928, when he discussed with his usual keenness the appointment of his successor and seemed to have in prospect a happy period of well-earned retirement. A virile personality, he had strong convictions and was not afraid to express them, when charm of manner and transparent honesty balanced his outspokenness. Long ago a new member of the health committee who questioned his veracity received the unexpected retort, 'If you don't withdraw that statement, I'll come round and pull your nose.' After receiving counsel in an undertone from his neighbour that the medical officer would probably be as good as his word, the member withdrew. In his younger days Boobbyer was no mean athlete. It is related how he and two colleagues, bored with the opening ceremonial of a public health congress in Edinburgh, paid a visit to the Castle where they came upon a sergeant instructing some kilted recruits in putting the weight. Presently the instructor addressed the silk-hatted befrocked trio, 'Perhaps one of you young gentlemen would like to have a try!' Boobbyer accepted the invitation, doffed his coat and hat and threw the weight a good ten feet further than the soldiers. The cold bath before breakfast at the age of 73 (on which his death followed) was typical of a man who preferred to live dangerously. He would not have liked to rust out."

Dr. Boobbyer married a sister of the architect Mr. Watson Fothergill by whom he had two sons and two daughters, all of whom survive him.

ALBERT MORTON MARTIN, M.B., B.S. DURH.,

CONSULTING SURGEON, ROYAL VICTORIA INFIRMARY, NEWCASTLE-UPON-TYNE.

THE death of Mr. Martin on the last day of the old year came as a shock to his numerous friends in Newcastle and district. Though he had not been well for the past two months it was thought that his health was improving and he was at work the day before he died. He had only retired from the active staff of the Infirmary in September last on attaining the age limit of 60 years, and had been looking forward to spending his retirement in the country of which he was so fond.

Albert Martin was born and bred a Northumbrian, and graduated M.B., B.S. Durh. with honours in 1890. After acting as house surgeon to the Ingham Infirmary at South Shields he returned to the Newcastle Infirmary as house surgeon, and soon after was appointed honorary assistant surgeon. His promotion was rapid, so that for 29 years he was full surgeon in charge of wards and the greater part of that time senior surgeon. For a period he was also surgeon in charge of the then existing orthopædic department of the hospital. In private he had an extensive consulting practice, and owing to his special knowledge of diseases of bones and joints his services were in great demand in cases of dispute arising out of the Workmen's Compensation Act.

Mr. J. Hamilton Barclay writes: "Having been Mr. Martin's private assistant for over ten years and having worked with him for long at the Royal Victoria Infirmary, certain characteristics stand out prominently in my mind. First, his wonderful surgical skill. He had, more than almost any one I know, the gift or faculty of making operations look easy and simple. While operations on the bones and joints were his favourite, yet he was perfectly at home in all operations of general surgery, and particularly in the region of the gall-bladder and the pelvic organs. To see him remove a torn semilunar cartilage through a small transverse incision was a revelation. His touch was wonderful; to a casual observer he might at times appear rather rough in his handling, yet I have never known him bruise or lacerate the tissues in his manipulations. Without appearing to he got through a morning list in a remarkably short time and without any fuss. He did not bother with many of the new and elaborate techniques but was satisfied with the technique that had served him so well in the past and the results showed that he was right, for his operation wounds healed perfectly. Secondly, his wise judgment and surgical sense. He was an excellent diagnostician and always seemed to know just when to operate. In my earlier days I was often astonished at his decision to 'sit' on a case overnight when to me it appeared to be urgent; but I soon found he was right. Last, but not least, his wonderfully bright and optimistic temperament. He was always buoyant and cheerful, even in the face of adversity, and he was always considerate and loyal to his juniors and colleagues. Whatever his assistant did in the wards was right. The Infirmary will be a poorer and a sadder place for his loss."

Mr. Martin's wife predeceased him; he is survived by two sons, one of whom has followed his father's profession, and two daughters.

Dr. **William Eidinow**, who died on Jan. 23rd, was 34 years of age, and qualified as M.R.C.S. Eng. in 1917 from the London Hospital, where he held the appointments of emergency officer and surgical clinical assistant. He served from 1917 to 1920 with the rank of Captain in the Royal Army Medical Corps, in France, Italy, and Montenegro, and was awarded the Italian Silver Medal for Valour. After demobilisation he took up a busy practice amongst the working classes of Islington.

Parliamentary Intelligence.

NOTES ON CURRENT TOPICS.

Collecting Charities (Regulation) Bill.

The debate on the second reading of the Collecting Charities (Regulation) Bill was resumed in the House of Commons on Tuesday, Jan. 21st.

Mr. **E. Brown** said that this was a measure to provide for the investigation and regulation of charities that appealed to the public for support. It fell into three main parts. Clause 1 gave power to the Charity Commissioners to inquire into the affairs of collecting charities. Clause 2 gave power to the Charity Commissioners to regulate collecting charities. Clause 3, which required to be turned inside out, might gravely injure certain operations of trade-unions. It provided that the Home Secretary might make regulations—unspecified and unstated—enabling him to do three things: (*a*) He might permit persons to make or cause to be made visits from house to house for the purpose of making appeals for support for any collecting charity. (*b*) Persons might be permitted to make, or cause to be made, in places of public entertainment or public refreshment collections for any collecting charity. (*c*) Any collecting charity might cause collecting boxes to be exhibited in any shop for the purpose of making appeals for support for the charity. What would be the position of organisations which might be formed for perfectly good causes if this Bill became law? The Home Secretary had received a deputation from the larger collecting charities, and he (Mr. Brown) understood that the right hon. gentleman had made an arrangement with them. But what would be the position of the smaller charities not represented on the deputation? Unless the House could get assurances about the form of Clause 3 it should, in his opinion, hesitate to give a second reading to the measure, because Clause 3 was so vague in its drafting that it constituted one of the worst samples of legislation by reference that the House had ever been asked to pass.

Sir **Kingsley Wood** said that this was an important Bill affecting the great charitable institutions of the country, and it called for scrutiny from every member of the House. A number of charities which called themselves national charities had been in communication with the Home Secretary at various conferences and had made certain objections to the provisions of the Bill. The Home Secretary had made some suggestions by way of meeting their difficulties. But the House ought to protect not only the national charities, but also the many small charities operating in particular localities. It appeared that if any county or county borough council liked to make representations to the Charity Commissioners, not on specific grounds, but because they had some sort of objection or complaint as regarded a specific charity, the Commissioners, without—at any rate for the moment—any specific right of appeal to any court of law, could put into operation the very drastic powers contained in the Bill. They could order any bank which happened to have the money of the charity to withhold payment to the people who actually invested their funds there, and could order the particular charity to be wound up. That was a very drastic power to give. The Departmental Committee on this subject had found that out of 80,000 charities only about 100 could be said to be preying on the public. That hardly justified the drastic provisions of this Bill. The London County Council took the view that if there was any question about the administration of charities they should be required to satisfy a competent authority and become registered. The Bill would have to be examined very carefully indeed in Committee. He hoped that the Home Secretary would see that nothing was done to interfere with the beneficent work of the very large number of small and large institutions of a charitable nature up and down the country.

Effect of Clause 3 on Finances of Charities.

Mr. **Philip Oliver** said that this Bill was considered, and especially the provisions of Clause 3, by the Northern Association of Hospital Secretaries last October. The Association was a very responsible body, and the meeting was the largest attended gathering that it had held. The secretaries and superintendents of 30 hospitals were present from towns like Manchester, Liverpool, Warrington, Bradford, Leeds, Sheffield, Hull, Chester, Stockport, and Oldham. The secretaries of all the great infirmaries and hospitals of these towns were very much perturbed indeed as to the effect of Clause 3 on their finances. A big hospital would almost certainly have what was called a workpeople's fund committee. Collections were made from door to door. There were other hospitals which had beds or cots supplied by particular districts. The person responsible was somebody who lived in the district. Under this Bill the regulation must provide that "no such visits or collections shall be so made or caused to be made . . . as aforesaid except by persons licensed for the purpose by such officer of the police as may be designed for the purpose." When the Bill was printed he (Mr. Oliver) went to see the secretary of one of the big Manchester hospitals, and asked him what the effect of that provision would be upon their voluntary collectors. He replied that they would refuse to go to the police at all. Why should voluntary collectors, giving up their spare time for this work, go to the police to be licensed? There was absolutely no justification for such a proposal. Another gentleman, who was secretary of a large body known as the Manchester and Salford Medical Charities Fund, had stated that the effect of this measure would be to cause sensitive-minded collectors to throw up the job. These considerations were very gravely perplexing the minds of those responsible for the big hospitals of the country. Why did not the Home Secretary, instead of producing this Bill with supervision, extend the existing legislation to charities which were not controlled by that legislation? The War Charities Act prohibited appeals by any charity unless it was registered, usually by the local authority. No charity was allowed to be registered unless it had a responsible committee of not less than three persons, unless it kept proper books of account, and unless those books were open to inspection. That was a perfectly rational system of control. Police supervision was very objectionable, and in any case would cast a heavy burden on the police themselves.

Amendments Promised in Committee.

Mr. **A. Short** (Under Secretary for the Home Office) said that in this Bill the Government were seeking to meet the demand put forward not only by the charitable organisations themselves, but supported by the recommendations of the Departmental Committee. The Home Secretary recognised that Clause 3 was by no means perfect. It rightly gave rise to anxiety and to questions founded on a desire to protect the interests of these great charitable organisations. His right hon. friend would be prepared in Committee to make drastic amendments to meet the views of the House as expressed in all quarters, and thereby secure, if possible, unanimity when the Bill passed through the Committee stage. It was proposed to amend the Bill so as to permit an appeal to be made to the High Court against an order of the Charity Commissioners for the regulation of a charity under Clause 2. They also proposed to permit an appeal to Quarter Sessions against a refusal to license on the ground of fraud or maladministration of the charity itself. The regulations would apply to all charities, but the war charities which were now governed by various Acts of Parliament would be exempted as provision would be made by amendment. The regulations would be based in principle on the recommendations of the Departmental Committee and would be in the form of those made by the Home Office, under the Regulation of the Street Collections, Police, Factories (Miscellaneous Provisions) Act, 1916. All charities, national and local, would be subject to the regulations. So far as the refusal of licences was concerned, they did not desire to cripple new enterprises, and they hoped to prevent an arbitrary refusal of licences and to ensure that they were not refused on arbitrary grounds. To prevent any discrimination against new enterprises, licensing officers would be required to grant a licence unless the person in respect of whom the application was made was under 21 years of age, was of bad character, or otherwise not a fit and proper person to be a collector, or where the charity was not being carried on in good faith for charitable purposes, or was not being properly administered, or was not keeping proper accounts of receipts and expenditure. The Home Secretary was most anxious that the regulations should be drawn in a broad and generous spirit, and that nothing in them should be calculated to cripple charities, national or local, which were above suspicion and where there was no suggestion of fraud. The regulations would be drawn in such a way as not to interfere with the creation of new charities. They would seek the coöperation of the great charitable societies, and would welcome the advice and assistance of all charities, large or small, in safeguarding the interests of all concerned. The regulations would be published, and they could be amended from time to time in the light of experience in order to meet the ever-changing needs of the community.

The debate on the second reading was adjourned.

Suggested Redrafting of Clause 3.

On Tuesday, Jan. 28th, the debate on the second reading of the Collecting Charities (Regulation) Bill was resumed.

Mr. **SHORT** (Under Secretary for the Home Office), replying to Sir **HERBERT SAMUEL**, said that the Home Secretary was fully conscious of the anxiety in regard to Clause 3 of the Bill, and realised that the measure ought to receive the general assent of the House as well as that of the great national and local charitable organisations. While he (Mr. Short) was not authorised to say that the clause would be withdrawn altogether, if the House would agree to the second reading when the Bill reached Committee the Government would redraft Clause 3 in such a manner as to cover the points which had been raised during the debate. Special consideration would be given to the interests of small domestic collections. The regulations would be drafted in broad general terms with a desire to safeguard the interests involved, and they would be laid on the Table of the House. If, when the Bill reached Committee and the regulations had been tabled, they could not get the general assent of the House, the Home Secretary realised that it would be futile to proceed with the Bill.

Mr. **WOMERSLEY** said that he had received a letter from a member of the Board of the British Hospitals Association stating that he was by no means satisfied with the Bill. He would like to know if the Under Secretary could assure him that he had received anything in the nature of assent to the Bill from that particularly influential body? In Grimsby every summer a particularly successful effort was made on behalf of the local hospital by means of a street carnival. A large number of collectors took part and they raised a good deal of money. During the week-end he had seen the Secretary of the Working Men's Committee responsible for this effort, and he had assured him that during the whole of the time that the collections had taken place they had never lost *one penny, although* thousands of pounds had been raised. If each of those collectors had to go to the police station to be registered the task of the Committee would be made absolutely impossible.

Mr. **SHORT** said that he did not think that the British Hospitals Association was a charitable organisation, but that it existed for the purpose of collecting statistics and so forth. He explained, however, that the Charity Organisation Society called together a large number of organisations—some 121 societies were represented, including a large number of hospitals—and some 216 members were present. The meeting passed a resolution unanimously in favour of the Bill as it was introduced into the House. He hoped that that statement would to some extent remove Mr. Womersley's anxieties. He repeated his promise to amend Clause 3 in order to satisfy the points raised in the debate and secure the general assent of the House to the Bill. With regard to collections, if they were house-to-house collections, under Clause 3 each collector would have to have a licence, but each collector would not have individually to apply for the licence. The licence would be applied for by the society for whom they were collecting.

The Bill was read a second time.

INDIANISATION OF INDIAN MEDICAL SERVICE.

On Jan. 22nd, replying to Major **GRAHAM POLE**, Mr. **WEDGWOOD BENN** (Secretary of State for India) stated that the progress of the Indianisation of the Indian Medical Service since 1924, the year in which the Report of the Lee Commission was published, was as follows: 1924, 150; 1925, 151; 1926, 161; 1927, 163; 1928, 165; 1929, 167. There were 127 Indians on Jan. 1st, 1928, holding temporary commissions in the Indian Medical Service who were not included in these figures.

MEDICAL EXAMINATION OF YOUNG PERSONS EMPLOYED AT SEA.

Miss **BONDFIELD** (Minister of Labour), replying to Sir **BASIL PETO**, said that the Draft Convention relating to the compulsory medical examination of children and young persons employed at sea, adopted by the International Labour Conference at Genoa in July, 1920, had been ratified by 21 countries, including Great Britain, Canada, and India.

CHILDREN (EMPLOYMENT ABROAD) BILL.

The Children (Employment Abroad) Bill was read a second time.

HOUSE OF LORDS.

THURSDAY, JAN. 23RD.

HOSPITALS AND ROAD ACCIDENTS.

The Road Traffic Bill was considered on report.

Requirements in Respect of Insurance Policies.

On Clause 35 Lord **LUKE** moved after subsection (1) to insert as a new subsection:—

> "Where any payment is made by an authorised insurer under a policy issued under this Part of this Act in respect of the death of or bodily injury to any person arising out of the use of a motor vehicle on a road and the person who has so died or been bodily injured has to the knowledge of the authorised insurer received treatment in a hospital in respect of the fatal or other bodily injury so arising, there shall also be paid by the authorised insurer to such hospital the expenses reasonably incurred by the hospital in affording such treatment to an amount not exceeding £25 for each person so treated."

He said that the people affected by this amendment were the great hospitals near trunk roads in which beds were filled with people injured in motor accidents to the exclusion of local patients for whom the hospitals were provided. In the great majority of cases no return of expenses had been made to the hospitals. This amendment was brought forward in Committee and met with such strong support from their lordships that it was only withdrawn on condition that it should be dealt with on report. In the interval they had been invited to visit the Ministry of Transport and they took with them an amendment which had been approved by the Voluntary Hospitals Committee of the King Edward's Hospital Fund. After consultations they thought that Earl Russell (in charge of the Bill) would be able to move the amendment, but they subsequently learned that he was unable to do so.

Viscount **KNUTSFORD** said that it would be a very great disappointment to the hospitals if the Government were not able to accept the amendment. Insurance companies had to fix their premiums to cover the cost of medical expenses, and it seemed unreasonable that because the expenses were incurred in a hospital that made no charge they should escape that part of the reasonable payment for the recovery of the patient. The hospitals did not want to make any legal charge against their patients, and they quite realised the legal difficulties, but they trusted Lord Russell to get over them.

A New Principle in Insurance.

Lord **PONSONBY** (Parliamentary Secretary to the Ministry of Transport,) said that the Government were sympathetic to the underlying principle of the amendment, and they only wished that it could be made practicable. They could not stretch this Bill, however, to comprehend too many subjects, and they could not make it a measure for paying back to the hospitals sums which they were being deprived of by the number of accidents brought to them. They felt that that was outside the scope of the Bill. It really involved an entirely new principle in insurance, and must necessarily increase the premiums. If, as stated by Lord Knutsford, the hospitals were reluctant to put forward any legal claim on a patient, how could the Government place the liability on the insurance companies in an Act of Parliament? To draft a clause to do that would be almost impossible, and to ask the Government to be responsible for this new principle was asking too much.

The Earl of **ONSLOW** appealed to their lordships to carry on with their intentions and see whether, even if the particular form of words were not approved, it would be possible on the third reading for something satisfactory to all sides to be introduced. Even if this were a new principle in insurance, was Parliament not always introducing new principles in legislation? This Bill was full of new principles.

The principle of this amendment was strongly recommended by the Voluntary Hospitals Commission in 1925. He would cite some interesting figures which showed the experience of the Royal Surrey County Hospital, of which he (Lord Onslow) was president. That hospital was situated near the Portsmouth road and was favourably—or perhaps he should say unfavourably—placed for the reception of road accident cases. The number in 1927 was 156; in 1928, 170; in 1929, 153. The average number of days in hospital of these road accident cases was 34; and there was a constant occupation during that time of 15 beds for these cases. As most of these were men, and they had only 70 beds for men, a very high proportion of the accommodation was taken up by this class of case. That being so, a very heavy expenditure was entailed on hospitals like theirs in this connexion. The hospitals made no complaint whatever of having to take these cases; it was their duty, but where compensation was paid it seemed not unfair that part of that compensation should go to the hospitals concerned.

Earl **Howe** said he hoped that the last word had not been said by the Government on this subject. If the strain on the hospitals became too great, and some of them had to put up their shutters, what would be the attitude of the Government then? The number of motor-cars in this country was not going to decrease, and there was not a word in this Bill as it stood that would increase public safety on the roads. Accidents, he thought, would tend to increase rather than to decrease in proportion.

Lord **Danesfort** said that unless the Government could assist the House in finding some practical solution of this urgent problem there would be deep and widespread disappointment and dissatisfaction throughout the country. The voluntary hospitals had done magnificent work for years. Their finances were greatly strained even before the advent of motor-cars; since the coming of motor-cars those finances had been more strained than ever. When under this Bill they were making provision for insuring third party risks they were really bound to do what they could to help the hospitals out of the great difficulties with which they were now faced.

Lord **Armstrong** said that, coming from the north, he would like to bear out what had been said about the experience of hospitals in the south. He was chairman of the Royal Victoria Infirmary, Newcastle, which had 550 beds. They had to reserve a ward of 30 beds entirely for motor accidents, and the cost to the infirmary they estimated at £5000 a year. He had read reports of several other hospitals in his area, and unless something could be done he felt that there would be great disappointment among the voluntary hospitals of the country.

Lord **Stanley of Alderley** said that the amendment did not involve a very exceptional or very wide extension of the insurance policy already provided for in the Bill. At present a man was liable for any accident which he caused. He was liable for the cost of medical attendance. If an injured person was taken to a private doctor or a private hospital or, he believed, to a poor-law infirmary, there could be no doubt that the insurance company would allow all the expense to which the person causing the accident was put in consequence of the accident. The only case—and that he understood from Lord Atkin was a doubtful one—where the liability might not exist was in the case of a voluntary hospital. Surely it was a very small extension of the principle which was admitted in the case of every other medical service to extend it to cover what was at least a moral and quite possibly a legal obligation upon a person causing an accident. To suggest that the amendment should be resisted because it would mean increasing the premiums which motorists had to pay was making a very large mountain out of a very small mole-hill. The cost of covering this extra liability would, he thought, be very small indeed.

The Earl of **Donoughmore** appealed most earnestly to the Government to accept the amendment now, even if they might have to alter the wording at a subsequent stage.

The Marquess of **Salisbury** said that unless the Government would announce their willingness to reconsider this matter before the third reading of the Bill he would be obliged to vote for the amendment.

Earl **Russell** said that the foundation of the case of those who had argued in favour of the amendment was not open to dispute. A perfectly serious and genuine effort had been made by the Government to draft a clause which would be free from fundamental objections, but frankly they had been unable to do so. This amendment meant that the insurance company was to have placed upon it a liability which was only a legal one in the sense that it was imposed by statute. It was no part of their original contractual liability to the insured person. That seemed to violate almost every principle of law. There was another aspect of the question which had struck him very strongly, and which he would ask those who were interested in hospitals to consider. Was it not rather difficult to go on talking about voluntary hospitals when they were compulsorily raising money by statutory obligation? It seemed that in their own interests hospitals were embarking on rather a slippery slope. They would be wise to be careful before they embarked on this point of view. If there was an increase in premiums which was directly due to this liability, and if it was in any way substantial, or if there was anything which caused a sense of grievance in the minds of motorists, it might very well be that voluntary subscriptions would fall off to a larger extent than these involuntary subscriptions would meet.

The amendment was agreed to without a division.

The consideration of Bill on report was adjourned.

HOUSE OF COMMONS.

WEDNESDAY, JAN. 22ND.

Slum Clearances.

Mr. **West Russell** asked the Minister of Health what programmes of slum clearance in the respective Tyneside local authority areas had been adopted and how many people in each case it was estimated would be rehoused.—Mr. **Greenwood** replied: Apart from schemes already approved, in regard to which I have given some information in reply to another question by the hon. Member, one scheme is now before me. It was submitted by the town council of Newcastle-upon-Tyne, and involves the rehousing of 945 persons.

Mr. **West Russell** asked the Minister of Health how many buildings had been acquired for demolition, how many buildings had been demolished, and new buildings erected in connexion with slum clearance schemes since April, 1925, in the Tyneside area; and how many persons formerly living under slum conditions had been rehoused under these schemes.—Mr. **Greenwood** replied: The information, so far as it is available, is given in the following return showing progress in connexion with slum clearance schemes in the Tyneside area from April 1st, 1925, to Jan. 1st, 1930:—

Local Authority.	Buildings which have been—		New dwellings erected.	Persons required to be re-housed under each scheme.
	Acquired for demolition.	Demolished.		
Wallsend T.C. ..	165	159	156	723

Lawson's-court Area.	—	—	—	246
Total ..	495	478	835	4717

THURSDAY, JAN. 23RD.

Small-pox.

Mr. **Day** asked the Minister of Health whether he could give the number of cases of small-pox notified since Jan. 1st, 1929, in England and Wales, giving separate figures for London and the number of fatal results.—Mr. **Greenwood** replied: During the 52 weeks ended Dec. 28th, 1929, 9066 cases of small-pox were notified in England and Wales (excluding London), and 1903 cases in London. Among these cases 39 deaths occurred which were classified to small-pox. These figures are at present provisional.

Psittacosis in Warwickshire.

Captain **Eden** asked the Minister of Health whether his attention had been called to the recent outbreaks of psittacosis in Warwickshire; whether any inquiry into the causes of the disease was being instituted; and what steps he proposed to take.—Mr. **Greenwood** replied: The answer to the first part of the question is in the affirmative. All recent alleged cases of this disease in this country that have come to the notice of my department have been studied, and in some instances medical officers of the Ministry have taken part in the investigations. The question of further administrative action will be considered as soon as the inquiries now in progress are completed.

Captain **Eden**: Is it a fact that there is at present no obligation to report these cases once they have been diagnosed to the medical officer of health, and does the right hon.

gentleman not think in view of the seriousness of the disease that notification ought to be made compulsory?

Mr. **Greenwood**: That may be so, but I imagine in all these cases of relatively rare diseases that as soon as they occur they do in fact report them to medical officers of health.

Dr. **Vernon Davies**: Will the right hon. gentleman consider the possibility of inviting all port medical officers of health to pay particular attention to all parrots being brought into this country?

No answer was given.

Slum Clearance.

Major **Nathan** asked the Minister of Health when he anticipated that the Government's projected Bill as to slums would be passed into law; and whether meanwhile he was refusing to consider and approve housing schemes submitted by local authorities.—Mr. **Greenwood** replied: I regret that I cannot at present add anything to the statement made on Tuesday by the Prime Minister on the subject of the first part of this question. As regards the second part, no schemes for providing new houses are being delayed in my department by the expectation of the new Bill; but in the case of slum clearance schemes I have in some instances suggested that in view of certain difficulties which have arisen it would be better to await the proposals which I hope shortly to submit to this House.

Operative Experiments on Living Animals.

Mr. **Lovat-Fraser** asked the Home Secretary the number of operative experiments on living animals, witnessed by the inspectors under the Cruelty to Animals Act, 1876, during the years 1924–28, inclusive.—Mr. **Clynes** replied: The number of operative experiments witnessed by the inspectors during the years mentioned was 769.

Sale of Skimmed-milk Cheese.

Mr. A. M. **Samuel** asked the Minister of Health what steps his department was taking to prohibit the sale of skimmed-milk Dutch cheese without the buyer being made aware at the time of purchase that it was not whole-milk cheese.—Mr. **Greenwood** replied: The sale of skimmed-milk cheese under any description indicating that it is whole-milk cheese would be an offence under the Food and Drugs (Adulteration) Act. I have no power to impose any further requirements as to the sale of this commodity.

Silicosis and Workmen's Compensation.

Mr. **Hoffman** asked the Home Secretary if he had decided to extend the silicosis order under the Workmen's Compensation Acts; and, if so, when would it come into operation.—Mr. **Clynes** replied: If, as I assume, my hon. friend refers to the proposed inclusion of employment on the machines known as Slack's machines under the Metal Grinding (Silicosis) Scheme, I have not yet come to any final decision. As my hon. friend knows, a deputation on this question has been received from the representatives of the workers and certain representations on the subject have been received from the Sheffield Employers Association who asked for an interview. This has recently taken place and I have just received a report of the discussion. I will give the matter my immediate consideration, and will communicate with my hon. friend as soon as a decision is reached.

School Medical Services.

Dr. **Vernon Davies** asked the President of the Board of Education if he had made any estimate of the increased personnel and extra cost for the school medical services necessitated by the compulsory raising of the school age.—Sir **Charles Trevelyan** replied: Although some extension of the existing arrangements will be necessary, I am advised that the raising of the school age will not in itself involve any material increase in the personnel and cost of the school medical service.

Dr. **Davies**: Does that mean that the Board of Education intends to work the present medical staff more fully than they are being worked at present?

Sir C. **Trevelyan**: No. I said that there was no reason to suppose that it would involve any material increase in the personnel; that is to say, there will not be an additional school inspection, and therefore no increase of work will be required.

Nursery Schools.

Mr. **Thomas Griffiths** asked the President of the Board of Education how many new nursery schools had been approved in the period July to December, 1929, inclusive; what number were now under construction; and the average initial cost of building a new school.—Sir **Charles Trevelyan** replied: Proposals for nine new nursery schools were approved in the period July 1st to Dec. 31st, 1929. So far as my information goes, there are nine schools at present under construction. The average cost of providing a new nursery school, on the basis of a number of recent examples, is about £34 per place.

Emigrants and Health Insurance.

Sir **Godfrey Dalrymple-White** asked the Minister of Health what arrangements, if any, the Government proposed to make to enable a person insured under the Health Insurance Acts who wished to settle in our Dominions to obtain a transfer of the values standing to his credit with his approved society.—Mr. **Greenwood** replied: There is already statutory provision under which the payment of transfer values may be made in respect of insured persons who emigrate to the Dominions and become insured in a society in the Dominions, subject to corresponding rights being given in respect of insured persons who come from the Dominions to this country. Any claim for the payment of a transfer value under these conditions should be made by the society through whom the emigrant is insured in the Dominions.

Women Factory Inspectors in India.

Major **Graham Pole** asked the Secretary for India how many of the 39 regular whole-time and nine part-time additional factory inspectors in India were women.—Mr. **Wedgwood Benn** replied: One of the whole-time inspectors is a woman. All the part-time inspectors are men.

MONDAY, JAN. 27TH.

Opium Consumption in Calcutta.

Major **Graham Pole** asked the Secretary of State for India if he could give information showing the consumption of opium per 10,000 of the population in Calcutta and how this figure compared with the League of Nations' Health Committee's estimate of the limit of legitimate consumption per 10,000 of the population.—Mr. **Wedgwood Benn** replied: The consumption of opium per 10,000 of the population in Calcutta was 86 seers in 1928-29. The League standard, which was suggested for the medical and scientific requirements of countries possessing a highly organised medical system and has little applicability to the conditions of India, was equivalent to about 6 seers per 10,000.

Germany and Psittacosis.

Dr. **Vernon Davies** asked the Minister of Health if he was aware that, owing to the fact that four deaths had taken place in Germany recently from psittacosis, the authorities there had placed a ban upon the import of parrots into that country and if he would consider the advisability of taking similar action in this country.—Miss S. **Lawrence**, Parliamentary Secretary to the Ministry of Health, replied: My right hon. friend has seen newspaper reports to the effect that the action referred to has been taken in Germany, but he has no official information on the subject. As regards the second part of the question, my right hon. friend is not at present in a position to add anything to the answer given on Jan. 23rd.

Sale of Poisonous Disinfectants.

Lord **Fermoy** asked the Home Secretary if his attention had been called to the increasing sale of poisons in the form of disinfectants and to the fact that suicides from drinking disinfectants had increased from seven in 1918 to 287 in 1928; whether this was a matter now being considered by the inter-departmental committee on the Poison and Pharmacy Acts; when he expected the report of that body; and whether he proposed to schedule such disinfectants among the lists of poisons or to take any other action to limit the free sale of such products.—Mr. **Clynes** replied: My attention has not been called to the increasing sales referred to by the noble Lord. The Report of the Departmental Committee on the Poisons and Pharmacy Acts set up by the Lord President of the Council is expected shortly and will be laid before Parliament. Under the existing law I have no power to add to the schedule of poisons, such powers being vested in the Pharmaceutical Society, whose action has to be approved by the Privy Council.

TUESDAY, JAN. 28TH.

Venereal Disease in the Army.

Mr. Cecil **Wilson** asked the Secretary of State for War whether his attention had been called to the statements in the official Reports on the health of the Army concerning the provision of prophylactic outfits for self-disinfection after exposure, and, in particular, to the statement in the 1925 Health Report on this subject, which showed that out of 968 cases of venereal affection 181 men endeavoured to use the prophylactic outfit but used it incorrectly, that 207 men used it correctly but were infected, and that 580 men, although carefully instructed, did not use the prophylactic; and if, having regard to the youth of many of the personnel of the Army, the repugnance of many people to the State provision of such prophylactic packets, and their doubtful medical value, he would order that such provision be discontinued.—

Mr. T. SHAW replied: I am advised that the method of prevention of venereal disease by means of early disinfection has been shown to be generally efficacious and it has therefore been retained with a view to reducing venereal disease in the Army.

Health of British Troops in Egypt.

Mr. CADOGAN asked the Secretary of State for War whether he was in a position to state where the troops which were destined shortly to leave Alexandria and Cairo were to be quartered; and whether he would give a definite undertaking that the British garrison in these two towns would not be moved until a proper water-supply and adequate arrangements had been made for the health of the troops in their new quarters in the canal zone.—Mr. T. SHAW replied: No general settlement has yet been reached with the Egyptian Government. The answer to the first part of the question is consequently in the negative. As regards the second part, the hon. Member may rest assured that adequate arrangements will always be made for the health and comfort of the troops.

Noise and Public Health.

Mr. FREEMAN asked the Minister of Health whether he intended to introduce legislation dealing with excessive noise caused by faulty machinery, sirens, hooters, mechanical appliances, and other forms of noise inimical to public health.—Miss S. LAWRENCE replied: Other considerations than those of public health arise in regard to such legislation, and in any event the commitments of the Government would render its introduction impracticable.

Pulmonary Tuberculosis in the Navy.

Dr. VERNON DAVIES asked the First Lord of the Admiralty the number of men granted pensions for pulmonary tuberculosis held to be attributable to the conditions of service during each of the last 10 years for which statistics were available; the number of men refused pensions as being non-attributable; and the total number of men in receipt of such pensions at the latest convenient date.—Mr. ALEXANDER replied: The numbers of men invalided for pulmonary tuberculosis and awarded attributable pensions and the numbers refused such pensions for each year since 1924 are as follows:—

	Granted.	Not granted.
1924	5	151
1925	2	187
1926	6	191
1927	18	162
1928	42	98
1929	177	83

Statistics for the years prior to 1924 and the numbers of men now actually in receipt of attributable pensions for pulmonary tuberculosis are not available and could not be compiled without a very considerable expenditure of time and labour.

Venereal Disease in the Navy.

Mr. CECIL WILSON asked the First Lord of the Admiralty whether his attention had been drawn to the statements in the official reports on the health of the Navy, which showed that pocket antivenereal outfits, or prophylactic packets for self-disinfection, were provided for the use of all ranks in the Navy, and that definite and detailed instructions were given to the personnel as to the technique of self-disinfection at the time of exposure to venereal infection, and subsquently in the ablution chamber; and if it was proposed to continue these practices in the Navy, having regard to the youth of many of the personnel, the repugnance of many people to the State provision of such facilities, and the fact that the official statistics for the Army showed that many men who had used the prophylactic outfit according to instructions had been infected.—Mr. ALEXANDER replied: The Committee of Inquiry on Venereal Disease, over which Lord Trevethin presided in 1923, concluded that substantial results may reasonably be expected to follow from these prophylactic measures. The Committee did not think that there is any justification for putting obstacles in the way of individuals who desire to procure disinfectants as a measure of protection against venereal disease. It is therefore proposed to continue to provide such facilities for the voluntary use of naval personnel. No coercion is employed to induce men to make use of these facilities. On the other hand, every endeavour is made to warn them of the dangers of promiscuous sexual intercourse by means of lectures, and to inculcate a healthful morale by the provision of organised games, recreation and entertainments at all ports, at home and abroad.

MANCHESTER ROYAL INFIRMARY.—The Trustees invite applications for the Dickinson Research Travelling Scholarship in Medicine, of the value of £300, tenable for one year. Candidates must be University graduates who have taken out their full course of clinical instruction in the Infirmary and in the University of Manchester, and have earned distinction in so doing.

Medical News.

UNIVERSITY OF OXFORD.—On Jan. 23rd the degree of Bachelor of Medicine was conferred on G. Secker-Walker.

UNIVERSITY OF CAMBRIDGE.—On Jan. 24th the following degrees were conferred:—

M.D.—Samuel Levy-Simpson (enacted 1928).*
M.B. & B.Chir.—E. L. Graff, J. I. Sapwell, and T. K. S. Lyle.
B.Chir.—C. D. Politeyan.*

* By proxy.

SOCIETY OF APOTHECARIES OF LONDON.—At recent examinations the following candidates were successful:—

Surgery.—M. Asaad, St. Mary's Hosp.; L. P. Clarke, St. George's Hosp.; K. Graftdyk, Leeds; H. W. Maurer, Charing Cross Hosp.; M. Naylor, Sheffield; M. S. Rappoport, London Hosp.; Z. Risk, Birmingham; T. G. Robinson, Guy's Hosp.; and F. A. Yarde, St. Mary's Hosp.

Medicine.—R. F. M. Child, St. Mary's Hosp.; V. J. H. Coidan, Beyrouth and Paris; C. E. P. Davies and W. J D'Rosario, Guy's Hosp.; K. Graftdyk, Leeds; C. B. Jennings, Charing Cross Hosp.; A. Kellner, London Hosp.; C. Skinner, Guy's Hosp.; and P. Somasunder, London Hosp.

Forensic Medicine.—T. Chandrasekharen, Madras and Manchester; A. P. Edwards, Liverpool; E. A. Freywirth, Heidelberg; C. B. Jennings, Charing Cross Hosp.; E. Lethem, Guy's Hosp.; and P. Somasunder, London Hosp.

Midwifery.—H. C. Halge, St. Mary's Hosp.; E. Jacomb, Birmingham; E. Lethem, Guy's Hosp.; and M. S. Rappoport, London Hosp.

The Diploma of the Society was granted to the following candidates, entitling them to practise medicine, surgery, and midwifery: R. F. M. Child, C. E. P. Davies, W. J. D'Rosario. A. Kellner, H. W. Maurer, T. G. Robinson, and F. A. Yarde,

ROYAL COLLEGE OF PHYSICIANS OF EDINBURGH, ROYAL COLLEGE OF SURGEONS OF EDINBURGH, AND ROYAL FACULTY OF PHYSICIANS AND SURGEONS OF GLASGOW.—At recent examinations the following candidates were successful:—

FINAL EXAMINATION FOR CONJOINT DIPLOMA.

W. B. Lee, Max Freed. D. P. Dow, Joseph Schwartz, Joseph Kinnear, O. V. Short, W. E. Faulkner, J. H. McGibbon, J. C. Coetzee, L. H. Abeyewardene, Margaret Leslie, T. G. Ward, E. O. Hagedorn, Florence L. M. Millard, H. S. Hamilton, George Henderson, R. F. L. V. Harvey, G. R. Parker, Pieter van der Lith, and Iskandar El-Aroussi.

The following passed in the undermentioned subjects:—

Medicine.—E. T. Buck, W. H. Taylor, G. L. Chadha, B. W. Advani, R. K. Pal, Kamil Kikhail, M. D. D. Jayawardana, Adam Paterson, and J. A. R. Lavoipierre.

Surgery.—B. W. Advani, Adam Paterson, J. A. R. Lavoipierre, N. Y. Labib, and Daniel Millar.

Midwifery.—H. O. Parkinson, W. H. Taylor, G. L. Chadha, S. J. B. Collins, T. Y. Bhide, R. T. A. Morrow, R. K. Pal, Kamil Mikhail, and M. K. Thiruvilangam.

Medical Jurisprudence and Public Health.—J. P. Walsh, E. R. Fothergill, C. M. Douglas, H. W. C. Robertson, T. F. Kirkpatrick, Loutfi Ahmed. A. W. Turnbull, J. T. M. Fenton-Fyffe, G. D. Morgan, G. L. Whitton, B. A. Armitage, and H. L. Lucas.

UNIVERSITY OF LONDON.—A course of six lectures on Cytology in Relation to Physiology and Pathology will be given by Mr. R. J. Ludford, D.Sc., at University College at 5 P.M. on Wednesdays, Feb. 5th, 12th, 19th, 26th, and March 5th and 12th.

GRESHAM LECTURES.—Four lectures on How England Learned to Control Disease will be delivered by Sir George Newman, at 6 p.m., on Feb. 4th, 5th, 6th and 7th, at Gresham College, Basinghall-street, London, E.C.

INNS OF COURT.—Among those called to the Bar on Jan. 27th was Dr. D. McI. Johnson, at Gray's Inn.

ROYAL LONDON OPHTHALMIC HOSPITAL.—The annual dinner of past and present students of this hospital will be held at the Langham Hotel, Portland-place, on Thursday, Feb. 13th, at 7 for 7.30 P.M., with Mr. J. Herbert Fisher, consulting surgeon to the hospital, in the chair. Tickets may be had from Mr. Rupert Scott, 70, Harley-street, W.

PREVENTION OF DEATH IN CHILDBIRTH.—In accordance with the will of the late Dr. Robert Thomas Nichols, the Royal Society of Medicine offers every three years a prize (being the accumulated interest on £2,200) open to any British subject, for a contribution towards the Discovery of the Causes and the Prevention of Death in Childbirth from Septicæmia. Work submitted for the third award must reach the Secretary of the Society (1, Wimpole-street, London, W.1) not later than Oct. 1st. Work published since Oct. 1st, 1927, may be submitted.

UNIVERSITY OF GLASGOW.—The Harry Stewart Hutchison Prize, of the value of about £50, for the best writing or writings embodying Original Research Work in a Branch of Medical Science relating to Children will be awarded in 1931. Medical graduates (of not more than ten years' standing from their first graduation in medicine) of all British, Home, and Colonial Universities may be competitors. Compositions must be submitted, in proper form, to the Clerk of Senate, not later than March 31st, 1931.

MINERS' GIFT FOR TREATMENT OF CANCER.—From the Notts Miners' Welfare Fund a contribution of £3500 has been given in the campaign in Nottinghamshire against cancer, expressly for the purchase of a quarter of a gramme of radium and the necessary appliances to enable the Council in charge to afford priority of treatment to miners and their dependants who may be certified for radium treatment.

LEAD POISONING IN LANCASHIRE.—Dr. W. E. Cooke, pathologist under the Lancashire Insurance Committee's scheme for providing free laboratory diagnosis services for insured persons, states in a report that during the past few months several cases of lead poisoning in the county of Lancashire have come under notice. The common factor in all cases is the habit of drinking from the hot-water service in the home.

THE German Society of Internal Medicine is to hold its forty-second meeting from April 7th–10th at Wiesbaden under the presidency of Prof. Volhard of Frankfurt a.M. The principal subjects put down for discussion are the Pituitary, to be introduced by Trendelenburg (Berlin) and Lichtwitz (Altona); and Focal Infection, to be introduced by Rosenow (Rochester) and Bieling (Frankfurt a.M.). Those who wish to take part are asked to communicate with Prof. Volhard at the Medical Clinic. Following this gathering is a meeting of the German Society of Pædiatrics from April 11th to 14th. Any questions relating to the exhibition, which will be held in common, should be directed to Herr Bürger, Städtische Kurverwaltung, Wiesbaden.

BRITISH COLLEGE OF OBSTETRICIANS AND GYNÆCOLOGISTS.—At a Council meeting held in London on Jan. 21st it was reported by the honorary secretary that a large number of names had been received from the Dominions in regard to the election of Foundation Fellows and Members of the College.—Memoranda concerning the use of anæsthetics in labour and also maternal mortality, drafted at the request of the Ministry of Health, were submitted to the Council by a special committee elected for the purpose and were passed by the Council.—It was agreed that the election of the Council by popular vote should take place in May as foreshadowed at the annual meeting held in December last.

DONATIONS AND BEQUESTS.—Lieut.-Colonel W. B. Brocklehurst, of Prestbury, near Macclesfield, left, among other bequests, £1000 to the Macclesfield General Infirmary Endowment Fund.—Mr. Arthur Jowett, of Windy Bank, Batley, Yorkshire, left £1000 to the Batley and District Hospital for the purpose of endowing a bed to be known as the "Arthur, Mary, and Carrie Jowett" bed; and £1000 similarly to the Dewsbury Infirmary.—Mrs. Mary Elizabeth Christie-Miller left £1000 to the Queen Charlotte Lying-in Hospital.—The Royal Manchester Children's Hospital has received £1000 from the executors of the late Mr. Christopher Higginbottom, and £1000 from the executors of the late Mr. Joseph Hugh Monk.—Mr. William Bell, of Wallasey, left £2000 to his niece, Katherine Jane Guthrie "to be used as she may think fit for medical research" and £100 to Victoria Central Hospital, Wallasey.

NATIONAL MARK MALT EXTRACT.—The following statement has been circulated from the Ministry of Agriculture: "With the coöperation of the Retail Pharmaceutists' Union, the Ministry of Agriculture and Fisheries has issued to over 7500 retail pharmaceutists in England and Wales a letter, inviting their coöperation in placing upon the market National Mark malt extract (with oil) which is now being produced by a large number of malt extract manufacturers in this country. The malt extract is made entirely from home-grown barley to very high pharmaceutical standards designed to ensure the maximum nutritive and medicinal value for the product. National Mark malt extract and oil has been available since Jan. 8th last, and already very encouraging reports have reached the Ministry of its reception by the pharmaceutical trade. The National Mark Malt Extract Scheme is of great benefit to the public in establishing guaranteed high standards for a food and medicine which is in universal demand. In order to be sure that they are obtaining the genuine article, all purchasers of National Mark pharmaceutical malt extract and oil should look for the dark blue ribbon and seal with a National Mark which is placed upon all genuine supplies."

Medical Diary.

Information to be included in this column should reach us in proper form on Tuesday, and cannot appear if it reaches us later than the first post on Wednesday morning.

SOCIETIES.

ROYAL SOCIETY OF MEDICINE, 1, Wimpole-street, W.

TUESDAY, Feb. 4th.—5.30 P.M., ORTHOPÆDICS. (Cases at 4.30 P.M.) 8 P.M., PATHOLOGY. Meeting at the London School of Hygiene and Tropical Medicine, Keppel-street, W.C. Communications: Dr. J. G. Thomson: The Cultivation of *Herpetomonas culicidarum*. Dr. P. A. Buxton: A Case of Extensive Destruction of Bone Resulting from a Chronic Ulcer of the Leg in a South Pacific Islander. Dr. Ordmann: Pneumococcal Infections in Johannesburg. Mr. R. Lovell: A Bacillus of the Salmonella Group Causing Abortion in Ewes. Demonstrations: Dr. J. T. Duncan: Specimens Illustrating Mycetoma and Blastomycosis. Dr. G. S. Wilson: Apparatus for the Continuous Passage of Gaseous Mixtures through Cultures of Bacteria in a Liquid Medium. Dr. G. S. Wilson: Apparatus for the Growth of *Br. abortus* in Atmospheres Containing CO_2.

WEDNESDAY.—5 P.M., HISTORY OF MEDICINE. Paper: Mr. F. Prescott: Spallanzani on Spontaneous Generation and Digestion. 8.30 P.M., SURGERY. Discussion on Intrathoracic Tumours. Openers: Mr. Tudor Edwards and Mr. W. H. C. Romanis. Followed by Dr. L. S. T. Burrell and Dr. F. G. Chandler.

THURSDAY.—8 P.M., TROPICAL DISEASES. Papers: Dr. M. F. Sorour: Bilharzial Lesions of Blood-vessels. (Illustrated by lantern slides.) Dr. J. Gordon Thomson: Notes on a Visit to the Antimalarial Work in Italy. (Illustrated by lantern slides.)

FRIDAY.—10.30 A.M., OTOLOGY. (Cases at 9.30 A.M.) Discussion on Brain Abscess. Papers by Prof. Neumann (Vienna), Mr. E. Miles Atkinson, and Mr. H. W. B. Cairns. Cases will be shown by Sir James Dundas-Grant and Mr. C. Hamblen Thomas. 5 P.M., LARYNGOLOGY. (Cases at 4 P.M.) Cases will be shown by Dr. Dan McKenzie, Mr. O. Popper, Miss McLeod, Mr. V. E. Negus, Mr. E. Watson-Williams, Mr. M. Vlasto, and others. 8.30 P.M., ANÆSTHETICS. Discussion on Anæsthesia in Thoracic Surgery. Openers: Mr. C Langton Hewer and Mr. I. W. Magill. SURGERY. Members of the Section of Surgery are specially invited to be present.

ROYAL INSTITUTION, 21, Albemarle-street, W.

FRIDAY, Feb. 7th.—9 P.M., Dr. Leonard Hill: Diving.

ROYAL MEDICO-PSYCHOLOGICAL ASSOCIATION.

TUESDAY, Feb. 4th.—2.30 P.M., Quarterly General Meeting at David Lewis Colony, Warford, Cheshire. Dr. Alan McDougall: The Why of Conduct. Dr. Richard Handley: Pineal Cysts. Major D. E. Dhunjibhoy: Types of Insanity in India.

LECTURES, ADDRESSES, DEMONSTRATIONS, &c.

ROYAL COLLEGE OF SURGEONS OF ENGLAND, Lincoln's Inn, W.C. (Hunterian Lectures).

MONDAY, Feb. 3rd.—5 P.M., Prof. Geoffrey Keynes: Radium Treatment of Carcinoma of the Breast.

WEDNESDAY.—5 P.M., Prof. J. Herbert Fisher: Perforating Injuries of the Eyeball.

FRIDAY.—5 P.M., Sir John Rose Bradford: Massive Collapse of the Lung.

FELLOWSHIP OF MEDICINE AND POST-GRADUATE MEDICAL ASSOCIATION, 1, Wimpole-street, W.

MONDAY, Feb. 3rd, to SATURDAY, Feb. 8th—MEDICAL SOCIETY OF LONDON, 11, Chandos-street, Cavendish-square, W. Tues., 4 P.M., Lecture by Prof. Hugh MacLean: The Present Position of Gastric Physiology and its Bearing on Gastric Diseases. No fee.—ST. MARK'S HOSPITAL, City-road, E.C. Thurs., 5 P.M., Clinical demonstrations by Mr. E. T. C. Milligan. No fee.—BROMPTON HOSPITAL, S.W. Sat., 3 P.M. (in the theatre), Dr. Batty Shaw will demonstrate on Allergic Pneumonia. No fee.—BETHLEM ROYAL HOSPITAL, S.E. Special course in Psychological Medicine. Tues. and Sat., lecture-demonstrations at 11 A.M.

NORTH-EAST LONDON POST-GRADUATE COLLEGE, Prince of Wales's General Hospital, Tottenham, N.

MONDAY, Feb. 3rd.—2.30 to 5 P.M.: Medical, Surgical, and Gynæcological Clinics. Operations.

TUESDAY.—2.30 to 5 P.M.: Medical, Surgical, Ear, Nose and Throat Clinics. Operations.

WEDNESDAY.—2.30 to 5 P.M.: Medical, Skin, and Eye Clinics. Operations.

THURSDAY.—11.30 A.M.: Dental Clinics. 2.30 to 5 P.M.: Medical, Surgical, Nose, Throat and Ear Clinics. Operations.

FRIDAY.—10.30 A.M.: Throat, Nose and Ear Clinics. 2.30 to 5 P.M.: Surgical, Medical, and Children's Diseases. Clinics. Operations.

SOUTH-WEST LONDON POST-GRADUATE ASSOCIATION.

WEDNESDAY, Feb. 5th.—4 P.M. (at St. James's Hospital, Ouseley-road, Balham, S.W.), Dr. Ronald G. Canti: Demonstration of the Cinematograph Film on the Biological Aspect of Radium.

UNIVERSITY COLLEGE, Gower-street, W.C.

Monday, Feb. 3rd.—5 P.M., Prof. A. V. Hill: Oxygen and the Recovery Process in Muscle and Nerve. (Third of four public lectures.)

KING'S COLLEGE HOSPITAL MEDICAL SCHOOL, Denmark Hill, S.E.

Thursday, Feb. 6th.—9 P.M., Mr. J. M. Bickerton: Diseases of the Eye in General Practice.

ROYAL NORTHERN HOSPITAL, Holloway.

Tuesday, Feb. 4th.—3.15 P.M., Mr. F. D. Saner: Colonic Ptosis and Its Results.

LONDON SCHOOL OF DERMATOLOGY, St. John's Hospital, 49, Leicester-square, W.C.

Tuesday, Feb. 4th.—5 P.M., Dr. S. E. Dore: Affections of the Hair and Hair Follicles.

Thursday.—5 P.M., Dr. A. M. H. Gray: Xanthoma. Herpes.

CENTRAL LONDON THROAT, NOSE, AND EAR HOSPITAL, Gray's Inn-road, W.C.

Monday, Feb. 3rd.—1.30 P.M., The Ear: Examination and Diagnosis.

Wednesday.—1.30 P.M., The Nose: Examination and Diagnosis.

ST. MARY'S HOSPITALS, Manchester.

Friday, Feb. 7th.—4.30 P.M., Post-graduate Lecture (at the Whitworth-street West Branch), Dr. C. P. Brentnall: Abortion.

SHEFFIELD POST-GRADUATE LECTURES ON CANCER.

Tuesday, Feb. 4th.—8.45 P.M. (in the Physics Lecture Room of the University of Sheffield), Sir Lenthal Cheatle: The Treatment of Mammary Carcinoma by Radiation.

SHEFFIELD POST-GRADUATE CLINIC.

Friday, Feb. 7th.—3.30 P.M. (at the Royal Infirmary), Dr. Barnes: Clinical Forms of Nephritis.

GLASGOW POST-GRADUATE MEDICAL ASSOCIATION.

Wednesday, Feb. 5th.—4.15 P.M. (at the Royal Hospital for Sick Children), Mr. A. MacLennan: Surgical Cases.

Appointments.

Nisbet, B. R., M.D., Ch.B. Edin., D.P.H., has been appointed Medical Officer of Health for Kilmarnock.

Certifying surgeons under the Factory and Workshop Acts: Broster, E. D., L.R.C.P. Lond., M.R.C.S. (Wirksworth), Fisher, A. R., L.R.C.P. Lond., M.R.C.S. (Dover); and Manning, H. P. O., L.R.C.P. Lond., M.R.C.S. (Faversham).

Vacancies.

For further information refer to the advertisement columns.

Accrington, Victoria Hospital.—H.S. £150.

Birmingham City and University, Joint Board of Research for Mental Disease.—Histological Asst. £4 weekly.

Birmingham General Hospital.—Res. Surg. Reg. £120–£140.

Birmingham, Queen's Hospital.—Third Phys. to Out-patients and Third Surg. to Out-patients. Each £50.

Bootle Borough Hospital, Derby-road.—Sen. Res. M.O. Also Two Jun. H.S.'s At rate of £200 and £125 respectively.

Bradford, Royal Eye and Ear Hospital.—Jun. H.S. £150.

Bristol Eye Hospital.—H.S. £150.

Bristol Royal Infirmary.—H.P.'s and H.S.'s, &c. Each at rate of £60. Cas. H.S. and Dental H.S. Each at rate of £80.

Buxton, Devonshire Hospital.—Asst. H.P. At rate of £150.

Central London Throat, Nose, and Ear Hospital, Gray's Inn-road, W.C.—Out-patient Statistical Registrar. First Asst. to Out-patients. Also Res. H.S. At rate of £75.

Chelmsford, County Council of Essex and U.D.C. of Chingford.—Asst. County M.O.H., &c. £800.

Chelsea Health Soc. and School for Mothers.—M.O.

Chester Royal Infirmary.—H.S. £150.

Croydon County Borough.—Asst. M.O., &c. £600.

Derby, Bretby Hall Orthopædic Hospital.—Asst. M.O. At rate of £150.

Derby, Derbyshire Hospital for Sick Children.—Res. M.O. At rate of £150.

Derby, Derbyshire Royal Infirmary.—Ophth. H.S. H.S. Also Asst. H.S. Each £150.

Doncaster Royal Infirmary.—Second H.S. £150.

Ealing, Borough of.—Asst. M.O.H. £600.

Eastbourne, Princess Alice Memorial Hospital.—Sen. H.S. At rate of £125.

Evelina Hospital for Children, Southwark, S.E.—H.P. At rate of £120.

Exeter, Royal Devon and Exeter Hospital.—H.P. At rate of £150.

Huddersfield Royal Infirmary.—H.S. At rate of £150.

Hull Royal Infirmary.—Cas. H.S. At rate of £130.

Ilford, King George Hospital.—Second H.S. At rate of £100.

Indian State Railways.—Dist. M.O. Rs. 650 per mensem.

Ipswich, East Suffolk and Ipswich Hospital.—Cas. O. £150.

King's Lynn, West Norfolk and King's Lynn Hospital.—Hon. Physician.

Leeds, Tuberculosis Sanatorium, Killingbeck.—Asst. Res. M.O. £250.

Liverpool, David Lewis Northern Hospital, Clinical School.—Med. Tutor and Registrar. £175.

Liverpool, Royal Liverpool Children's Hospital, Myrtle-street.—Res. Cas. O. £250.

London Jewish Hospital, Stepney Green, E. Cas. O. At rate of £150.

London School of Hygiene and Tropical Medicine.—Demonstrator in Division of Bacteriology and Immunology. £400.

London Temperance Hospital, Hampstead-road, N.W.—Cas. O. At rate of £120.

Macclesfield General Infirmary.—2nd H.S. At rate of £150.

Manchester, Ancoats Hospital.—Res. M.O. £150. Also Orthopædic H.S. Also H.S. Each at rate of £100.

Manchester, Park Hospital, Davyhulme.—Jun. Res. M.O. At rate of £200.

Manchester Royal Infirmary.—Dickinson Scholarships, Research Travelling Scholarship in Medicine. £300. Also Pathology Scholarship. £75.

Miller General Hospital, Greenwich-road, S.E.—Res. M.O., Cas. O., and H.P. At rate of £250, £150, and £125 respectively.

National Hospital, Queen-square, W.C.—Hon. Dental Surgeon.

Newcastle-on-Tyne, Wooley Sanatorium, near Hexham.—Asst. M.O. £350.

Newcastle-upon-Tyne, Royal Victoria Infirmary.—Six Jun. Surg. Regs. Each £150.

Northern Rhodesia, Roan Antelope Copper Mines, Ltd.—Jun. M.O. £900–£1000.

Norwich, Norfolk and Norwich Hospital.—Hon. Surg. Also H.S. £120.

North Middlesex Hospital, Edmonton, N.—Second Radiographer. £250.

Nottingham Hospital for Women.—H.S. At rate of £150.

Oxford City.—Deputy M.O.H. £600.

Plymouth, South Devon and East Cornwall Hospital.—Hon. Asst. Surg. for Obstet. and Gynæcological Depts.

Royal Northern Hospital, Holloway, N.—H.S., Res. Out-Patient Cas. O. and Anaesthetist. Each at rate of £70.

St. Bartholomew's Hospital, E.C.—Clin. Asst. to Venereal Dept. One Guinea per session.

Salford Royal Hospital.—H.S. At rate of £125.

Sheffield Royal Hospital.—Ophth. H.S. Also Res. Anæsthetist. Each at rate of £80.

Sheffield Union Hospital.—Res. Asst. M.O. £250.

Stirling District Mental Hospital, Larbert.—Jun. Asst. M.O. £300.

Stoke-on-Trent City Education Committee.—Asst. School M.O. £500.

Stroud General Hospital, Glos.—H.S. At rate of £150.

Taunton and Somerset Hospital.—Jun. House M.O. At rate of £100.

Walsall County Borough.—Asst. M.O. £600.

Warrington Infirmary and Dispensary.—Jun. H.S. £175.

Westminster Hospital, Broad Sanctuary, S.W.—Asst. Surg. Reg. At rate of £50. Also Orthopædic Surgeon.

Windsor, King Edward VII Hospital.—H.S. At rate of £100.

The Chief Inspector of Factories announces a vacancy for a Certifying Factory Surgeon at East Linton (E. Lothian).

Births, Marriages, and Deaths.

BIRTHS.

Dendy.—On Jan. 19th, at Glyn Eithin, Mumbles, the wife of Dr. E. H. Dendy, of a daughter.

Halliwell.—On Jan. 21st, at Welbeck-street, W., the wife of Arthur C. Halliwell, F.R.C.S., of a son.

Miall-Smith.—On Jan. 22nd, to Dr. Gladys Miall-Smith, of Welwyn Garden City, the wife of Dr. H. J. B. Fry—a daughter.

Petit.—On Jan. 22nd, at a nursing home, New Malden, the wife of Dr. Petit, "Dunurlin," New Malden, of a son.

Warburton.—On Jan. 22nd, at Cotley, Streatham Hall, Exeter, the wife of P. D. Warburton, M.R.C.S., D.P.H., of a son.

Whitman.—On Jan. 24th, at Stoneboro' Cardiff, the wife of Dr. V. E. Whitman, Gold Coast Medical Service, of a daughter.

MARRIAGES.

Purnell—Goldsmid.—On Jan. 25th, at the Parish Church of St. Nicholas, Chiswich, Purnell Purnell, M.R.C.S., L.R.C.P., of Leigham Court-road, Streatham, to Ivy Florence, only daughter of George Campbell Goldsmid, of Bedford Park, Chiswick.

DEATHS.

Bell.—On Jan. 22nd, John Henderson Bell, M.D., of 3, Carlyle-square, London, S.W.3.

Boobbyer.—On Jan. 21st, suddenly, at Wellington-square, Nottingham, Philip Boobbyer, M.D., in his 73rd year.

Eidinow.—On Jan. 23rd, suddenly, at Ferncroft-avenue, Hampstead, N.W., William Eidinow, M.R.C.S. Eng., L.R.C.P. Lond., late of Colebrook-road, Islington, N.

Jones.—On Jan. 24th, at Aviemore, Hanwell, and of Cravenhill, W., Henry Cadwaladr Jones, L.D.S. R.C.S. Eng., aged 56.

Riddell.—On Jan. 24th, at his residence, Westfields, Sandbach, Dr. Robert Riddell, aged 61 years.

Wallace.—On Jan. 22nd, at his residence, Wallacefield, Belle Vue-road, Paignton, Dr. Abraham Wallace, aged 80 years.

N.B.—A fee of 7s. 6d. is charged for the insertion of Notices of Births, Marriages, and Deaths.

Notes, Comments, and Abstracts.

THE HISTOLOGICAL BASIS OF HEALTH.*

II. CELL-DIFFERENTIATION; THE NERVOUS SYSTEM IN RELATION TO HEALTH.

BY PROF. J. BOEKE,
DIRECTOR OF THE LABORATORY OF EMBRYOLOGY AND HISTOLOGY OF THE UNIVERSITY OF UTRECHT, HOLLAND.

As soon as we begin to discuss the problems of development and growth and their bearing on the problem of health, we must concentrate our thoughts on the wonderful phenomenon of the gradual differentiation of the cellular units. Growth may be represented by a mathematical formula, and identified as a chemical process. The formula of Robertson may be used as well for cellular growth as for the relation of the different organs to the body in growth, as long as we take into account only that part of the process which we may safely compare with the physico-chemical processes in nature, and try to trace the broad outlines of the chemical changes underlying growth. But as soon as we speak of the differentiation of the tissues, which leads us to an ever-increasing and ever more complicated inter-relation of the parts of the body to the body as a whole, and a much more complex relation of the organism to the outside world, we have approached one of the fundamental problems of existence. The endowments which bring us into relation with the external world make our internal life so complex that we feel that no mathematical formula will ever describe these relations. We touch the fundamental mysteries of existence; we are hovering on the outskirts of our human conceptions, and we shall never press beyond them, even when perhaps in time the limit to which we are able to go may be moved a little farther back, and some of the things which are at present utterly mysterious and incomprehensible will be comprehended and explained so that we may express them by a formula.

Differentiation—the Secret.

In differentiation lies the secret of life, of death, of health, for it is the most intrinsic factor of the organism. Without differentiation no life is possible, but death is the price. In 1911 Carrel, the well-known experimentalist, took a small piece of tissue from the living developing egg of a fowl, put it under a cover-glass in a drop of sterile nutritive fluid and kept it there at a temperature of 38° C. It remained alive and continued to grow and every day a small piece of the living culture was cut off and put into a fresh drop of the nutritive fluid. These pieces of living tissue continued to grow, and a number of them are still growing after 18 years. If all the living tissue produced by the growth of this small original piece of embryonic tissue had remained alive and growing at the same rate as the few pieces left to survive, a quantity of living material would have been produced many times as large as the terrestrial globe. Thus a piece of embryonic tissue continues to grow and has now been growing for a longer period than the life-duration of the fowl from which the original piece was taken. But it does not differentiate; it simply grows and multiplies and is practically immortal. If the piece of tissue had remained in the embryo, it would in the course of a few weeks have developed into a chicken—viz., into an organism of a distinct, harmonious, and differentiated form. But with the inauguration of this differentiated form death has come into action. Even in its sheltered environment the duration of life of the common domestic fowl is not more than six to nine years.[1] The same thing is seen in cultures of different cell-types outside the organism. In the ordinary plasma and fluid media the general character of the outgrowth of different cell-types taken from the living organism varies with, and is more or less characteristic for, each cell-type. Lewis assures us that it is now possible in most instances to identify the outgrowth—i.e., the specific cell-type involved, by the patterns formed by the cells in their relation to one another. Nevertheless, as a rule, differentiated cells lose their peculiar character, and grow out as common elongated branched cells without a distinct differentiation. They never form differentiated organs or functional units as in the body.

Differentiation, therefore, is the leading feature of the organism. Development is nothing but differentiation; we may define it as physiological division of labour and as morphological division of substance, but these are merely two aspects of the same thing, and in life they are actually inseparable. The synthetic cause of differentiation is, of course, the organism itself, but in the last analysis all differentiations are probably the results of chemical changes in the protoplasm and in the metaplasmic substances. So we may conclude that, in general, differentiation and diversity of cells originate in a diversity of relationships between nucleus and protoplasm. The relation between the size of the nucleus and the amount of protoplasm in differentiated cells and in functional units is nearly always quite different from that in undifferentiated cells. This change in the nucleo-protoplasmic relation alters the assimilative powers of the protoplasm and the autocatalyst level, so that the regenerative power of the tissues of any given species diminishes with their differentiation. The more highly differentiated the tissue, the less is the variety of tissues to which it can give rise when injury calls forth repair. In general, the potential morphological complexity of a cell stands in inverse relation to its degree of physiological differentiation (Robertson). Morphological differentiation may be the consequence of preceding physiological differentiation, followed by the assumption of specialised function, and this implies the performance of more and more limited functions, and so the exercise of more limited morphological potentialities.

But these are only generalities, and in the end do not give us any clear insight into the relation of differentiation to the problem of health. Even the remarkable relation between the nuclear ratio in the cells and the occurrence and frequency of cell division, important as it is in itself, does not throw much light on the problem. Of the highest importance, however, is the influence which a number of substances in the body, especially hormones, exert on the differentiation of the tissues. Normal differentiation during development is the result of hormonic influences; in mammals the maternal hormones may pass into the developing embryo and alter its differentiations, and the sex-hormones of the male embryo of a pair of twins in cattle may pass into the body of the female embryo and alter its secondary sexual characters (free-martins). Even the histological type of the epithelia of the adult body may be changed by hormones introduced into the body; a diet characterised by the absence of vitamin A may cause the epithelia of different mucous membranes to become stratified. Embryonic tissues may form hormones which cause other embryonic tissues coming into contact with them to differentiate in a certain way. The important feature of this process of induction seems to me to be that the differentiation induced is a differentiation other than that of the cells producing the hormones themselves. The hormone produced by a certain cell does not influence the cell itself in its differentiation, but may cause other cells, apparently as highly specialised as the cell itself, to alter their developmental course of differentiation and form another organ or functional unit.

We may safely say that everywhere in the processes of differentiation hormones play a most important part and, indeed, even the characteristics of the human race have been put down to the action of the different hormones produced by the endocrine organs. These hormones may actually enter into the composition of the protoplasm of the cells which they affect, and so become an essential constituent of the living substance. But even if we can trace a certain differentiation down to the action of a distinct hormone, the character of the differentiation itself is not in the least explained, nor is there an answer to the question why and how during development and growth the different hormones and other substances, by which those processes seemingly are regulated, are formed just where and when they are needed, so that the harmonious form of the organism is developed and remains harmonious during growth.

The same thing may be said of malign tumours. It seems very probable nowadays that these tumours arise as the result of stimuli which cause an abnormal proliferation of cells, with all its mediate and immediate effects. Thus the application of soot or tar to the skin may induce cancer of the skin in mice and, as Bonne showed, in monkeys, and indeed in man, and a number of substances of various kinds may induce this hyper-differentiation and cell proliferation. Among these are different hormones and substances (as the "auxetics" of Ross in tar) which cause inflammatory reactions and abnormal cell proliferation, while such other substances as tethelin cause retardation of the growth of the cancer cells. We could, therefore, try to bring the problem of cancer growth down to that of the nuclear ratio and the autocatalyst level, and so to the general problem of growth, and to an acceleration of senescence of the hyper-differentiated cancer cells. But the cancer problem is so extensive and difficult that I must confine myself here to these generalities, for every detail of the problem would require a lecture in itself to make it clear and to discuss it.

The Histological Basis of Health in the Nervous System.

At first sight no other element of the human body shows so many contradictions, when looked at from this point of view, as the nervous system. Nervous tissue, according to Child, has an exceptionally high metabolic rate and, as is well known, is extremely sensitive to lack of oxygen. On the other hand, even in inanition the nervous tissue resists destructive forces longer than any other. The cells of the nervous tissue possess a very high nuclear ratio, not only in development but also in the adult stage. And yet, after they are formed, the nerve-cells as a rule do not proliferate any more; they remain unaltered as long as the body itself lives, whereas most of the body cells have a far shorter life duration than the body as a whole. So the nerve-cells are permanent, and yet no cells show so markedly the effects of old age. Indeed, by a number of authors senescence and physiological death is attributed chiefly to the breakdown of the nervous tissue, death through old age being a cerebral phenomenon due to alterations of the nerve-cells. On the other hand, longevity, as exhibited by man and different species of animals, is, according to Friedenthal, in close correspondence with the "cephalisation-factor"; that is, with a high degree of development of the nervous system and of the ratio of the weight of the brain to the weight of the body. Seen from a morphological standpoint, the nerve-cells are among the least differentiated of animal cells; seen from a physiological standpoint, they are the highest differentiated cells of the animal body, and their function is the most finely adjusted and equilibrated function of the organism. Once formed, they show a marked tendency to remain unaltered during the lifetime of the organism, and yet in tissue cultures of embryonic tissues the nerve-cells are almost the only ones to show a distinct differentiation. As Lawrentjew showed quite recently, a nerve-cell in tissue culture may show a real innervation of a mesoblast cell by an outgrowth which penetrates into the mesoblast cell and forms an end-organ in the protoplasm. Nervous tissue is the only tissue which shows strongly marked regenerative powers in mammals, even in adult animals. The nerve-cells are extremely sensitive to lack of oxygen, yet only exceptionally do we see blood-vessels in close connexion with nervous elements, the capillaries as a rule remaining at some distance from the nerve-cells while the large arteries do not even enter the central nervous system. Nerve-cells, as far as we can judge, keep their form unaltered from youth to old age, and yet the functions of what we call our memory require a constant changing of the finer structure of the cells and their connexions as long as we are capable of learning something new. In short, we seem to see contradictions everywhere; every problem we have discussed takes on quite a different aspect when applied to the study of the nervous system.

---

* Being the second of two lectures (illustrated by lantern slides) delivered in London under the Chadwick Trust (slightly abridged).

[1] A case is reported of a cock surviving for 20 years.

Can we apply to the nervous system the idea of harmony between the elements constituting the body? As early as 1877 G. H. Lewes, in his book on the Physical Basis of Mind, conceived the idea of a struggle for life between the various cells constituting the organism and a consequent physiological selection of the fittest elements. Roux afterwards took up this conception and utilised it to interpret the differentiation of the nervous system. At first sight we are sorely tempted to say that Lewes was right, and that especially in the nervous system this struggle for life is raging from the beginning to the end of life, and that by this struggle the entire function of the system is regulated, although, of course, not in the sense of the original conception of Lewes 60 years ago.

The tissue in the central nervous system is differentiated into two kinds of cellular elements: (*a*) the ganglion cells, the true nervous elements, with their cell processes—the branched dendrites—conducting the stimuli towards the cell body, and the neurite or axon conducting it to other nerve-cells or to the peripheral nerves (which are nothing else but bundles of these neurites); and (*b*) the neuroglia cells, supporting elements, not used in the processes of transmission of nervous stimuli but of the highest importance for nutrition. The ganglion cells are often in very close connexion with neuroglia cells, which enclose the ganglion cell as a capsule and thus separate it from the surrounding tissue which carries the nutritive blood-vessels. So the ganglion cell is dependent on these capsule cells for its nutrition and oxygen-supply, and there is established a very intimate and harmonious connexion between them; the neuroglia cells, as Holmgren showed, often sending into the ganglion cells processes by which nutritive agents may be introduced into the protoplasm of the ganglion cells and dissimilation products expelled.

When old age sets in, there often seems to spring up between the two kinds of elements a disharmony, a struggle, in which the ganglion cell loses ground and shrivels, while the capsule cells multiply, push into the cell body of the ganglion cell and eat it up, until the shrunken ganglion cell is nearly filled with capsule cells, and in the end perishes and disappears. This contest occurs both in apparent health and in certain diseases. This process of *neuronophagy*, or the eating up of the ganglion cells, is one of the most interesting phenomena of the incipient senescence of the nervous system, and one of the most suggestive phenomena of the alterations which help to bring the life of the organism to a close.

Harmony in the Nervous System.

Neuronophagy is not in reality a struggle for mastery between the nervous elements and their supporting cells; it is simply a supreme effort to keep up the harmony, which is in danger of being broken by the diminishing vitality of the ganglion cells as the result of the incipient dissolution of old age. This wonderful harmony of function between the neuroglia elements and the nerve-cells is seen everywhere in the nervous system. One of the contradictory phenomena of the central nervous system is that the ganglion cells, which have a high metabolic rate and are extremely susceptible to lack of oxygen, are, as a rule, not surrounded by blood-vessels like, for example, the muscular elements, but the blood-vessels nearly always lie at some distance. Here the nutritive function of the neuroglia cells is shown in the most striking way. We often find an arborescent glial cell which is attached very firmly to the wall of a blood-vessel by one of its cell processes; with its cell body it is applied as closely as possible to a ganglion cell, covering it as far as possible by its branching cell processes. We can only interpret these extremely suggestive pictures by supposing that substances are passing from the blood-vessels through the protoplasm of the glial cell to the protoplasm of the ganglion cell and vice versa, just as in the case of the capsule cells.

Properly to exercise the nervous function—the conducting and transformation of nervous stimuli—the ganglion cell must not only be supplied with abundant nourishment and oxygen, but the conducting cell processes, the neurites, must also be sheltered and isolated from injurious influences, chiefly chemical, in the surrounding elements. Here, too, the glial cells are of the highest importance. They encircle the axons and form isolating substances of a lipoid character —the myelin—which enwrap the neurites. During the development of the nervous system the glial cells grow out from the central nervous tube and form a syncytial arrangement with the outgrowing nerve-cell processes themselves, following them to the end-organs, and in this syncytium they form the same isolating substances in order to keep the nerve-fibres free from injury and able to fulfil their function properly. When the more important parts of the nervous system come into function (after birth) the glial cells show such a marked acceleration of chemical activity that many of them are filled up entirely with the products of these chemical dissociations, loosen themselves out of the continuity of the glial system, and are found as "granule cells," lying free between the other elements of the nervous tissue. That in pathological cases these cells become more abundant and form a typical feature of irritated parts of the brain is no argument against the view that all these phenomena are to be explained as so many efforts to preserve the harmony and equilibrium between the functional and the nutritious elements.

No other tissue in the body presents such striking instances of this harmony between form and function as the nervous system, just because its function is the most complex and the most finely adjusted of all. Let me illustrate this by one of its most striking examples. The branched nerve-cells (multipolar cells) in the central nervous system are, as a rule, distinguished in different places by their peculiar form and arrangement. Indeed, the regular function of the parts of the nervous system depends not only on the form of the cells but in no less a degree on their arrangement, as the function of a watch depends not only on the form of the wheels but also on their arrangement in a definite order. For instance, in the cortex of the cerebellum there is a very remarkable arrangement of the cells which shows the same character throughout the whole cortex, whilst the form and shape of the cells, the extension and form of the cell processes, and their place in the cortex is as fixed as the arrangement of the different elements. It forms a pattern, a structure of the most strongly marked regularity. This we can understand when we bear in mind that one of the functions of the cerebellum is to regulate and coördinate the stimuli sent out by the cerebral cortex, so that coördinated movements of the different parts of the body result. Now in most animals after birth the movements are, for the greater part, not yet coördinated, and the coördination develops only slowly. The definite regular arrangement of the cells in the cortex of the cerebellum also develops very slowly. But a chicken, for example, must be able to stand, walk, pick up its own crumbs, and drink water as soon as it is hatched; in short, its movements must be coördinated immediately after birth. Yet two days before birth the cerebellum, which has only had such a short period for development, is still in an extremely undeveloped embryonic state. Development of the regular structure sets in all at once and the cells change to their definite form as a flower unfolds itself out of the bud when the sun is shining. They change place, arranging themselves in their definite pattern so quickly that they seem to fall through the surrounding glial tissue like raindrops from the sky, and leave hollow strands behind them. Within 24 hours the embryonic mass of cells is changed into the definite structure characteristic of the adult cerebellar cortex, and when the chicken is hatched it is able to live its own life, to walk, to run, to eat, and to take shelter under the wings of the mother hen.

The same phenomenon may be met with everywhere in the cerebral cortex, though the rate of growth is usually not so quick as in the avian cerebellum. The chief and most important factor of growth in the central nervous system is that it is an organised growth, that there is formed everywhere a distinct and most complex structure in which every cell has its allotted place and forms its own special synapses and which changes its features in every part of the brain, so that a specialist may tell from which region of the brain a section is taken by looking at a microscopic preparation made from it. In this process of growth there is nothing to indicate that a struggle between the different cells is going on, in which the "fittest" or "strongest" cell survives and takes the place of its weaker brothers, as was the dogma—the slogan—of biologists in the nineteenth century. On the contrary, we see everywhere the most exquisite harmony, in which every detail of structure has its own value according to the relation of its function to the function of the whole. When we study the development of the structure of the brain and its histology from this point of view, we can understand why it is impossible that there should be a constant renewal of the elements of the nervous system like that of many organs where, even in such compact structures as the epithelia, a continuous covering of the underlying tissues without defects is necessary and a constant dying-off and renewal of the cells is taking place. Every ganglion cell has its allotted and fixed shape and place, and when a part of the brain has reached its definite structure this must be fixed and permanent during the life of the cells which have combined to build up the structure. When a cell is lost by senescence, inflammation, or neuronophagy its place remains empty and cannot be filled up by another element. Thus, the loss of nervous elements in senescence is and must be irreparable and we can understand why many authors saw in this destruction of the nervous elements the true cause of natural death. On the other hand, the process of growth must be otherwise than in those organs in which a constant renewal and increase of cellular elements takes place. The brain is fully developed far earlier in life than the other tissues of the body. After it has been fully formed the ganglion cells of which it is built up seem to be fixed, unalterable units.

Memory and Mental Development.

And yet the functions of what we call our memory require a constant changing of the elements of the nervous system. The question of memory and learning and mental development is a very difficult and complicated one, which includes a number of different fields of investigation. We enter here upon the domain of psychiatry, of the higher consciousness, of the central and peripheral consciousness, of the subconscious mind; in short, upon the domain of the mind and of all these conceptions and terms in which the things of the mind are discussed. There is just now only a very vague and remote connexion between these conceptions and the terminology of psychiatry and the anatomical facts of neurology. The reflex theory of Sherrington, laid down in his masterly work on the integrative action of the central nervous system, based upon the fundamental principles of neurology and reflex action of Hughlings Jackson and Mott, the anatomical conceptions of the "horme" and "mneme" of Monakow, the anatomical facts and descriptions of Kinnier Wilson, of Nissl, of Winkler, of Magnus, have been pushed into the background by the psycho-analysis of Freud and the phenomenology of Jaspers, and according to the newer psychiatry the pathology of the mind seems to depart farther and farther from the anatomical basis, built during fifty years by the incredible labour and energy of a host of neurologists. Even the biochemist of the future, according to Mathews, has to be more than an electrical engineer; he must be a poet and a psychologist as well.

Even when we fully acknowledge the truth of what the phenomenologists say: that neurology has not yet been able to give us a sound and solid basis of anatomical facts upon which to build conceptions of mind and memory, there is no need to leave this solid ground. Material changes in the histology of the nerve-cells must be responsible for the permanent changes in mind and its behaviour towards the world. But these changes will, of course, be found only in the most intimate and delicate structure of the protoplasm of the cells, and will leave the general form and constancy intact. In the first place, while the cells as physiological units remain independent of each other, delicate threads, growing out from the neurite processes, travel through the glial tissue, reach other cells, and become connected with these by extremely delicate endings—the synapses of Sherrington. In this way new connexions are formed between the different cells, new paths along which the nervous stimuli may pass from one cell to another. Already existing threads may branch and thus reach new cells, and it is clear that in this way, while the cells remain unaltered, their form does not change, and the structure of the whole keeps its character, there arise new possibilities of stimulation and association by which the mental activity is enlarged and new associative properties are created.

The only difficulty lies in the assumption that these association fibrillæ grow out actively and independently as new collateral threads. For immediately the question arises: by what influence are these delicate fibrillæ, lost in the dense thicket of glial fibres and other nerve-cell processes, guided to the nerve-cell with which they establish a new connexion? Many investigators (Monakow, Nissl, Held) have supposed that they do not grow out independently, but that there exists throughout the nervous system a sort of fundamental network of living substance, exceedingly delicate, which unites all the nervous elements in a syncytial mass, and in which new paths for the conduction of the nervous stimuli may be differentiated. Others, however, conceive the outgrowth as an independent cell process growing out from the cell and reaching the other cell, guided by glial tissue cells and by extremely weak electric currents (or neurobiotactic influences, as Kappers supposes), but remaining an independent thread from beginning to end, because in their preparations they do not see anything which might be interpreted as the morphological substratum of these influences. Here we need only state that these outgrowing threads are formed and that by them new associations may be built up.

In the second place, the conducting apparatus of the cells themselves may be altered, and the existing connexions between different cells change their structure, thus causing the stimuli to pass more easily and quickly along one path than along another. Here we enter upon the much-debated and still debatable domain of the internal structure of the nerve-cells and its bearing on the problem of the conduction of the nerve impulses and the generation of new impulses. The nerve-cells may be connected with each other by their cell processes. Such a cell process may end in a sort of ramification which envelops the protoplasmic body of the nerve-cell with which it is connected. In certain cells these ramifications may be coarse and form a calyx-like investment to the cell body; in other places the pericellular fibres of the terminal ramification are very delicate and form a fine arborisation. Where these fibrils come into contact with the surface of the cell, they may end in small button-like enlargements or varicosities. In all cases we say that the nerve-cells are linked together by a synapse. Although the physiological changes—the nerve impulses—are propagated, stepping over, as it were, from one cell to the other at each synapse, there is evidence that in the transmission of nerve impulses from one cell to another a block always occurs at the synapse, causing a slight arrest or delay in transmission, and that nerve-impulses pass the synapse in one direction only. Apparently the nerve impulse is changed in passing from one cell to another. Is this change permanent and unalterable?

Those morphologists who regard the nerve-cells as independent units usually regard these synaptic connexions as consisting of dead matter, a sort of cement substance gluing the terminal buds or ramifications to the surface of the cells with which the endings of the nerve processes are in contact, or as a sort of transverse membrane across the conducting structures, which are then regarded as more fluid (Sherrington). No alterations in this dead matter seem to be possible, and the conducting substance of the afferent cell processes would be entirely separated from the conducting substance of the nerve-cells to which they are glued. Now this would be very difficult to understand. It seems impossible to conceive a stimulus passing from one nervous element to another through a non-living membrane or a cement substance without disintegrating. There must be living substance between. Even the hypothetical synaptic membrane of Sherrington must be an arrangement of units of the living substance. This living substance must be able to transmit the nervous stimuli. Now, as far as we know at present, the histological evidence tends more and more towards regarding, as the real conducting apparatus of the nervous elements, the exceedingly delicate fibrillæ inside the protoplasm of the nerve-cells and their cell processes. These neurofibrillæ are found throughout the whole nervous system everywhere where nervous impulses are conducted in a definite direction. In the peripheral junctions, where the impulse has to be transmitted to a muscle-fibre or a sensory impulse has to be transmitted from a tactile cell to the sensory nerve-fibre, we find an intermediate structure, a very delicate protoplasmic network, connecting the neurofibrillar structure with the protoplasm of the end-organs (the muscle-fibre or the tactile cells). So in the peripheral junctions we find a real protoplasmic connexion between the two, with a structure enabling it to transmit the nervous stimulus.

When we regard the connexion between the nerve-cells in the central nervous system—the synapse—as consisting of living substance in and through which the nervous stimulus may be transmitted, we must make clear both the possible mode of transmission of this stimulus and also the physiological independence of the nerve-cells and the anatomical nature of the synapse as a secondary connexion differing in character from both the connected parts. The only way to do this is to regard the intervening substance of the synapse not as a sort of non-living cement but as a living substance, in which there is a structure akin to the intermediate substance of the peripheral junctions and which connects the neurofibrillary endings of the cell processes with the conducting apparatus of the nerve-cell itself. As a living substance the synapse may obtain such an arrangement of its living units composing the conducting protoplasmic apparatus as is more suitable for a quick and unweakened transmission of the stimulus. Inside its protoplasmic substance there may be formed a more complex organisation of its linear (neurofibrillar) structure, or a transient part of this linear structure may become fixed; in short, inside the synaptic living substance the conducting apparatus may become more and better organised. In this way it might be possible to explain those alterations of the transmission of nervous stimuli by which stimuli coming from particular cells are enabled to follow a particular path of transmission more quickly and easily than another path, and so to give rise to one distinct complex of reflex actions. This phenomenon—that a certain stimulus, unimportant in itself, gives rise to a distinct set of reflex actions, that in their turn may be the cause of other well-ordered actions and so regulate or alter our mental activity—creates what we call memory, our remembrance of things in the past that regulates and governs our existence, our life.

Thus, even in a permanent structure like the nervous system there is room for alteration, for growth, and for amelioration (and on the other hand for deterioration), within the boundaries of normal structure. By this is determined its intrinsic value for our health and existence.

Agduhr, who investigated the structure of the spinal cord and the nerve-roots, suggested that even the unalterability of the nervous system as a whole after birth may not be so absolute as is generally assumed. He subjected young dogs to a very severe and prolonged muscular training, and counted the nerve-cells and nerve-fibres belonging to the muscles which were thickened and strengthened by the training process. He found a distinct progressive alteration of the number of nerve-cells and fibres and concluded that, even in a nervous structure already formed, a branching of nerve-fibres and an increase of the number of nerve-cells is possible, at least in the much simpler structure of the spinal cord and spinal ganglia. Further investigation is necessary here, and indeed we are still on the threshold of this field of inquiry, but it may be sufficient to show that, even in the permanent structure of the nervous system, health is a process of movement and never of stagnation. It is only in this way that we can understand all those other phenomena of the nervous system, the phenomena of regeneration which in the higher animals are studied almost exclusively in the nervous system, the curious phenomena of the vicarious action of the different parts of this system after one part of it has been destroyed, the action of the glial elements in disease, and so many other problems of the nervous system in health and disease.

ILLUMINATION AND PRINT.

AT a meeting of the section of State Medicine of the Royal Academy of Medicine in Ireland held on Jan. 17th, the President, Prof. W. D. O'Kelly, urged the need for fixing school standards of adequate and correct illumination and not merely minima; he thought a foot-candle-meter should be used on a dull day and actual readings taken in the rooms. No child should be condemned to sit the whole year in a badly lighted place; pupils should be changed round during the day unless conditions were ideal. Artificial illumination was merely a stop-gap arrangement in existing buildings. Children under 12 should not be allowed to use school books with letters less than 1·75 mm. high, nor less than 1·5 mm. high at any time during school life. If it were necessary to economise he would prefer a page and type twice the size printed on a cheaper paper. One of the objections to the use of small type was that the ascending and descending parts of the letters were reduced more than the other portion. The eye picked out in reading the upper part rather than the whole letter, and as all the capitals were ascending letters and ascending lower case letters occurred more frequently than descending ones it was rendered doubly difficult for the child to read small type. When illumination was insufficient a great strain was thrown on the eye and damage frequently resulted.

The Irish type was, said Prof. O'Kelly, pleasing to the eye. Irish texts set up in roman type did not look so well, especially when "h" was substituted for the aspiration mark. He did not think the Irish type would be replaced by the Roman any more than the Venetian had replaced the English black letter, although the former was a simpler type. The Gothic varieties, although more difficult, were more pleasing. The print in school books in the Saorstat was good in the majority of those he had examined; it averaged 10–11 point. But he would prefer 12 point. If used in model by-laws why not in school books? In three of the seven grammars on the approved list the print was too small; in the exercises of one of these the small letters were only 2 mm. high. Dr. M. O'Leary, however, remarked that even in schools which conformed to the rules laid down by the Local Government Department the percentage of cases of bad vision was nearly as high as in those which did not; it had recently been stated that 50 per cent. of the eye troubles in children were hereditary and were not in any way due to faulty illumination in the schools.

CICELY NORTHCOTE TRUST.

THE social service department at St. Thomas's Hospital, founded in memory of his sister, by the late Mr. H. S. Northcote, publishes its twentieth report this year. The Fathers' and Mothers' Club, which provides classes on all kinds of home-making for mothers—while their children are tended for them in another room—and debates and social evenings for fathers after working hours, is as popular as ever with the parents who own it, but is sadly in need of money to enlarge its space. Nearly 9000 patients have been visited in the wards by Northcote Trust workers, who try to establish what the Americans call a "100 per cent. contact," so as to smooth the path for them from the warm shelter of the wards to the stark realities of life at home. Where necessary, the ward visits are followed up by home visits, and any kind of assistance is given, varying from the provision of an ambulance to all arrangements for convalescent treatment and the care of the family while the patient is away. The Northcote Trust almoner is responsible for arranging the supply of insulin to diabetics who have been discharged from hospital. She has to decide whether it can be obtained through a panel doctor or through hospital at a reduced price, or, if not, how the patient can meet the demand on his purse. Another group of patients over whom the Trust watches with especial care are the cancer cases. All patients discharged with cancer are visited at regular intervals to make sure that they are not in want, and that they have the necessary dressings, diet, and nursing comforts. During last year, for instance, four wheeled-chairs were given to cancer patients, over 1200 of whom were watched. The Northcote Trust Hostel admits unmarried mothers and pregnant girls who need treatment, and tries to give both mother and baby as good a start in life as possible. Thanks largely to the influence of America, social service has come to be recognised as one of the most important aspects of a hospital's work. The pioneer efforts of the Cicely Northcote Trust have been appropriately recognised this year by a request from Australia for a visit from the head worker, Miss Macintyre, to inaugurate a centre of work and training at the Melbourne Hospital. We hope it will not be long before every hospital in this country considers itself inadequately equipped unless it has a social service as efficient and as devoted as that at St. Thomas's Hospital.

A DOCTOR IN A NOVEL.

ON Oct. 18th, 1929, Dr. Luke Serocold, one of a firm of three practitioners who shared the work of a small country town with one rival, paid six professional visits to private patients; attended a meeting of the Town Council as Medical Officer of Health (part-time); and performed a radical mastoid operation. At 2.30 A.M. he was watching the death of his senior partner; at 11.45 P.M. he was giving the anæsthetic while his assistant delivered a child.

Dr. Serocold, it must be admitted, is only a character in fiction created by Miss Helen Ashton, whose novel centreing round his day's work, has just been published.[1] But he will be recognised as a typical family doctor, who has reached an age when he is even more interested in the struggles of his patients to adapt themselves to their environment, than in their physical disorders. We see their problems through his kindly eyes, mourn with him for his doomed friend, and rejoice in the brave indiscretion that costs him his best patient. Some readers of the book might have preferred to observe the behaviour of the neighbours and patients and to draw conclusions about their emotional life, instead of only seeing them reflected in the doctor's musings. The majority, however, will be content to follow Dr. Serocold through his day's work with the respectful attention he deserves, rejecting the suspicion that in real life he might have been a bore. Since women doctors in fiction are often incredible, a word of praise is due to Miss Ashton for her sketch of Dr. Jean Gordon, a young assistant of pleasant demeanour, who is competent without taking herself too seriously.

Hunterian Lecture

ON THE

SURGICAL TREATMENT OF CARCINOMA OF THE CERVIX.

Delivered before the Royal College of Surgeons on Jan. 27th, 1930,

BY VICTOR BONNEY, M.S., M.D., B.Sc. LOND.,
F.R.C.S. ENG., F.C.S.A.,

ASSISTANT GYNÆCOLOGICAL SURGEON TO THE MIDDLESEX HOSPITAL; SURGEON TO CHELSEA HOSPITAL FOR WOMEN.

THE modern surgical treatment of carcinoma of the cervix dates from 1895 when Ries, of Chicago, suggested a method of radical extirpation by the abdominal route, the main feature of which was the dissection of the ureters from out the neighbourhood of the growth. This operation was actually carried out by W. W. Clark in 1896, and shortly afterwards Thring, of Sydney, devised a similar procedure. In 1898 Wertheim, of Vienna, began to perform an operation on the same lines as those suggested by Ries, but he improved it by placing clamps across the vagina, whereby the growth was cut off from the uninvolved vagina beneath it so that the risk of cancer infection was avoided. His operation was looked at askance by the gynæcological surgeons of that time and provoked much adverse criticism; but by rare courage and persistency he succeeded in forcing its value on a doubting surgical world, and it is by his name that this great advance will for ever be known.

The greatest feature of Wertheim's contribution to surgery was that it doubled the percentage of patients who could be operated on. Up to the time when his operation was accepted, patients with carcinoma of the cervix, if able to be operated on, were subjected to vaginal hysterectomy, and in not more than 25 out of every 100 presenting themselves was the growth early enough to permit of operation; whereas, by the new procedure 50 per cent. or more were able to be surgically treated, and further, the more than doubled operability rate was accompanied by a much increased five year survival rate.

The first British surgeon to perform it in Great Britain was Cuthbert Lockyer in July, 1905, shortly before which date he had assisted Wertheim himself to perform it at Plaistow Hospital.

My first Wertheim's operation was undertaken in the spring of 1907, since when I have performed it 382 times. Compared with operations on the stomach, gall-bladder, and so forth, series of which running into four figures have often been published, this may appear to be a small number, unless it is remembered that carcinoma of the cervix, though too prevalent, is not very common, forming only about 1·4 per cent. of the diseases peculiar to women: moreover, the clinical material from which large series of cases can be abstracted is far less abundantly supplied to the individual surgeon in this country than on the Continent, where the professorial system places an enormous amount of it at the sole disposal of the professor. My colleague, Comyns Berkeley, also carried out the first of his series in 1907, since when he has performed it between three and four hundred times, with results very similar to my own. Certain other British surgeons about that time also began to practise it, and from then till now it has been frequently performed in this country. It may be wondered, therefore, why it is that so few papers dealing with the results of long series have not been published here. There are two reasons. The first is that though many surgeons here have essayed it, comparatively few (for one reason or another) have done so on a large scale. The second is, that very few of those who have performed it in quantity have persisted in the labour of keeping in close touch with their patients over the long period of years necessary before the results of a series can be properly presented. The difficulty of keeping in touch with these patients, belonging as they mostly do to the poorer classes whose habitation is constantly changing, is very great. The Continental professor has at his command a number of assistants to whom he can delegate this work, whereas the British surgeon works more or less *solo*; and if he wishes to keep in touch with his patients he must do it for himself. Some sort of follow-up system is beginning to be organised at most large hospitals, but this is of quite recent date and still very imperfect.

RESULTS OF THE OPERATION.

Of the 382 Wertheim operations that I have carried out 284 were performed by the end of 1924, and this number therefore are available for examination on the basis of 5 years' freedom from recurrence. My results are as follows:—

Died of operation	47 (16·5 %)
Recurrence before 5 years	107
Lost sight of before 5 years	12
Died of other diseases before 5 years ..	8
Well at end of 5 years	110
	284

Operative Mortality.—The high operative mortality was the principal objection raised against Wertheim's innovation. He had 30 such deaths in his first 100 operations. Increasing experience and technical skill enabled him to bring the rate down to under 10 per cent. in his later cases. This has been, I think, the experience of all surgeons who have performed it largely. In my own case it has certainly been so, thus, I performed:—

			Per cent.
From 1907 to 1915,	110 operations	with 22 operative deaths	..20
„ 1916 to 1924,	174 „	„ 25 „	„ ..14·3
„ 1925 to 1929,	98 „	„ 8 „	„ .. 8·1

Two questions are at once suggested. (1) To what are these deaths due? (2) What brings about their diminution?

The Causes of Operative Deaths.—The severity of the operation itself is less a factor in the death-rate than are the conditions general to the patient herself and local to the seat of the growth. A very considerable proportion of women suffering from cancer of the cervix are in very poor health, quite apart from the growth; in fact, I believe that very few develop cancer in that situation until their general condition from other causes has considerably deteriorated. The average age of these patients, moreover, is somewhere about fifty years. Of the 382 women I have operated on 14 were over sixty years, and 3 over seventy years. There were 23 patients under thirty-five years of age, 6 of whom were under thirty, but my general impression is that not much more than one or two of these young persons were in normal health—quite apart from their disease. The poor general quality of the clinical material with which the surgeon practising Wertheim's operation has to deal is paralleled in cases of cancer of the stomach and rectum; the surgeon in all three instances is handicapped from the start.

Nor is the local condition less important. The majority of cancers of the cervix are heavily infected by the time the patient seeks advice and some of them very intensely; so that the risk of post-operative infection of the operation area, even with the utmost precautions, is always present. How intense such infection may be is shown by the fact that Berkeley and I had amongst our early cases several examples of gas-gangrene of the abdominal wound exhibiting the typical black sphacelus of the muscles and foul effervescing pus, with which later on the war made all surgeons familiar.

Of the 382 patients on whom I have operated 55 died as the result of the operation, and the causes are as follows:—

Traumatic shock	20	Paretic obstruction ..	3
Hæmorrhagic shock ..	5	Peritonitis	2
Septic shock	13	Embolism	2
General sepsis	2	Suppression of urine ..	1
Pyelonephritis	3	Anæsthetic	1
Thrombosis of femoral artery	1		55
Secondary hæmorrhage ..	2		

The term "septic shock" describes that state of collapse which follows operative disturbance of an area already heavily infected and which is probably due to the manipulation suddenly launching into the circulatory fluids of the body a heavy dose of toxins or bacteria. It is most typically seen in cases in which the operative manipulations are too slight in themselves to cause shock, as, for instance, simple drainage of a big pelvic abscess. The symptoms differ from those of traumatic shock in that the patient is not pallid, but flushed and sweating, and the temperature is markedly raised. Death occurs within 48 hours as a rule. Including the deaths from general sepsis, peritonitis, and secondary hæmorrhage (which is always due to sepsis) it is seen that 19 of the deaths were due to infection, against 20 due to the sheer trauma of the operation.

Under the heading "hæmorrhagic shock" fall those cases who died as the result of bleeding during the operation. The loss of blood was not due to arterial or venous bleeding, but to a persistent oozing universal to the whole area operated on. These cases are fortunately rare, for the oozing cannot be stopped by forceps or ligature, and all that the surgeon can do is to get through the operation as quickly as possible, in which endeavour he is constantly being thwarted owing to his landmarks being obscured by blood.

Three deaths from pyelitis are less than might be expected, seeing the frequency with which infection of the urinary tract complicates convalescence. This frequency is partly due to the absolute paralysis of the bladder which always follows the operation, and which may endure for as long as two or three weeks, during all of which time catheterisation is necessary; but it is chiefly due to the bareing and displacement of the bladder whereby it backs into the free space left by the extirpation—a space which probably always becomes more or less infected.

REASONS FOR THE PROGRESSIVE DIMINUTION IN OPERATIVE MORTALITY.

My operative mortality has fallen from 20 per cent. in my first 100 operations to 8 per cent. in my last 98, and this fall has not been due to any change in my standard of selection. It is the result of a number of small improvements in the technique of the operation, each of which has been devised to shut the door against the repetition of some difficulty or disaster of the past—in short, it is due to utilised experience. I will therefore proceed to discuss in some detail those points in the technique of the operation by observance of which I have been able so markedly to lower my operative mortality.

TECHNIQUE OF OPERATION.

The Anæsthetic.—For an operation in which traumatic shock accounts for over 30 per cent. of the operative deaths, the advantage of spinal anæsthesia to block shock impulses is manifest, and I have employed it since 1910, combined with full ether anæsthesia. The reason for preferring ether to gas and oxygen is that it is a powerful stimulant, and tends to counteract the fall in blood pressure which spinal anæsthesia occasions—an important point, because so many of the patients are in poor general condition to start with. The utmost possible relaxation of the abdominal muscles is necessary in order that the surgeon can see what he is doing, and no one should undertake the operation unless he can count upon his anæsthetist to attain this safely. I have had the advantage of having as anæsthetist for the large majority of my cases Dr. Herbert Charles, whose unique experience with myself and Comyns Berkeley comprises nearly 700 of these operations.

Sterilisation and Packing of the Vagina.—The important step of sterilising the vagina is best effected by packing the canal with gauze soaked in violet green, the adoption of which for this purpose in 1916 was immediately followed by a remarkable lessening in post-operative sepsis. The vagina should be packed under the anæsthetic before the abdomen is opened, and it is essential to pack it tight right up to its vault, for unless the canal is made into a solid column, the separation of the bladder and rectum from it is rendered difficult and dangerous.

Protection of the Abdominal Wound.—It is probably impossible to absolutely sterilise a foul growth, and if any organisms are transplanted from it to the abdominal wound the latter will break down more or less seriously. To protect it, Berkeley and I, as a result of our unfortunate early experiences, soon began to wrap its edges with sheet rubber. I now use two layers of rubber, the first of which is attached to the skin by clips, whilst the second goes on with the retractor to which it is attached, and covers the whole thickness of the wound edges. An automatic retractor is a necessity in order that the operation area may be fully exposed and clearly seen, for many of the patients are very stout and the surgeon is working at a great depth surrounded by highly important structures, an accidental wound of which immediately deprives the patient of half of her chances.

On Separating the Bladder and Rectum.—The bladder and rectum should be separated by sense of touch; the former with the thumb kept pressed against the solid column formed by the packed vagina so that the flat of the thumb-nail rests against the bladder; and the latter by the first and second fingers, the pulps against the vaginal column, and the flat of the nails against the bowel. If the bladder is opened by accident, it should be sutured and the bladder should be drained, but a fistula may form. If the bladder is greatly thinned in the process of separation it may necrose later with the same result. I have had five vesical fistulas, of which two closed spontaneously. Accidental holeing of the rectum is a great disaster, for most of these cases die.

On Finding the Uterine Artery.—Fix forceps to the stumps of the cut round ligament and ovariopelvic ligament respectively, and get them pulled outward, meantime the uterus is pulled to the opposite side. With the fingers tease away the light cellular tissue in the upper part of the broad ligament until the external iliac vein is exposed. Work down the side of the pelvis, looking for the cord of the hypogastric artery which is running parallel to and inside the vein and about an inch below it. In easy cases the uterine artery can now be seen coming off it at right angles. If you cannot see it, feel for and expose the ureter as it runs on the posterior peritoneal surface of the broad ligament, and be sure that the artery is not running parallel to and just above it, as it sometimes does. If you still cannot see it, gently push the index finger down into the broad ligament just outside the ureter and see if you can hook forwards under the artery and lift it up. If this fails, as it may do when the tissues lateral to the cervix are indurated by growth or inflammation, work back along the hypogastric artery till you come to the internal iliac trunk and ligature that.

On Exposing and Isolating the Ureter.—Having divided the uterine artery close to its branching from the hypogastric artery, gently peel its distal end towards the uterus and the ureter will be exposed underneath it. If you have had to ligature the internal iliac, follow the ureter forwards from where it lies on the peritoneum to its junction with the bladder, cutting forwards with scissors in a line outside and parallel to it. You will presently divide the uterine artery; its proximal end will not bleed, though its distal may do. Pick up the distal end and peel it back to the ureter as before. It is necessary to completely isolate the lower two inches of the ureter up to its junction with the bladder, for unless this is done the cardinal ligament which lies below it cannot be properly exposed or safely divided. More than two inches should not be isolated if it can be avoided, for fear of necrosis.

On Grafting the Ureter.—In advanced cases the ureter may be so embedded that it cannot be dissected, or may be nipped about half an inch from the bladder and dilated above the stricture. If the growth is not irremovable on other counts (as it often is) the best course, instead of wasting time in dissecting out the ureter, is to divide it above the point of embedding, and having completed the extirpation, graft it into the bladder. I have done this deliberately nine times, and once more on the single occasion when I accidentally cut the ureter, and in all ten of the operations the graft held. Ureteral fistulæ following the operation are due to necrosis of the duct by the combined effects of "isolation anæmia" and septic infection of the extirpation cavity. They develop in from five to ten days after the operation. I have had eight such, four of which closed spontaneously; two were treated by nephrectomy, one was successfully grafted into the bladder, and one remained open until the patient died of recurrence.

On Dividing the Cardinal Ligaments.—All the foregoing steps in the operation lead up to and are the necessary preliminary to what is in effect the essence of the operation—namely, the division of the cardinal ligaments. These ligaments consist of a couple of broad fan-like fibromuscular expansions which, rising one on each side from the lateral wall of the vagina, are attached to the side wall of the pelvis. Not only do they fix the vagina, so that until they are divided the mobilisation necessary before it can be cut sufficiently low down is impossible, but the main lines of growth infiltration and permeation run outwards in their upper part, so that the division needs to be made as near the pelvic side wall as possible. A surgeon who has never properly performed Wertheim's operation has never seen these ligaments for no other operation exposes them, so deeply hidden are they by the structures that overlie them. The ureters rest on their front and upper surfaces, whilst their back and lower surfaces are separated from the pararectal tissues and lateral rectal ligaments by fibro-fatty wads of tissue. It is unnecessary to clamp them before dividing them, as the few vessels they contain are small and can be picked up with forceps. Not until they are divided from top to bottom is the vagina really free. The division, except in the easiest of cases, has to be carried out largely by sense of touch, and it is this, I think, that makes Wertheim's operation, of all recognised surgical procedures, the most difficult to become expert in. During the division, which must be done with long bent scissors, the vagina and uterus should be strongly pulled to the opposite side, and the index finger should be hooked under the ligament both to hold it up and to guard against the rectum being injured.

On Suturing or not Suturing the Vagina.—I began by following Wertheim, who only removed enough of the vagina to cover the cervix; but for a long time now I have removed the whole or nearly the whole of it. In my earliest operations (again following Wertheim) I left the vagina open and packed the extirpation cavity with gauze; later on I gave up packing but left the vagina open; and later still I took to suturing it up and leaving the cavity undrained. If, however, the whole of the vagina is removed it is impossible to suture the open end, which is practically at the vulva, because the bladder overhangs it too much, so that I have now gone back to packing the extirpation cavity, using gauze wrung out of a 1 in 2000 solution of flavine, which is removed in 24 hours via the vulva. I believe this to be the best technique, for it saves the time taken to suture the vagina, whilst flavine is somewhat of a styptic besides being a strong antiseptic.

Removal of the Regional Glands.—Wertheim himself removed the regional glands only when he deemed them to be cancerous, but from the beginning I have removed them as a routine. There are two groups of these glands on either side: (*a*) those lying along the inner side of the iliac veins, and (*b*) those lying in the obturator fossæ. The second of these two groups is the most important, for it is the earliest to become permeated and it is also the one most likely to escape observation because the contents of the obturator fossa are hidden by a screen of tissue in whose upper edge runs the hypogastric artery. The glands along the iliac veins are easily seen and stripped off, but to get fair access to the obturator fossa it is necessary to remove the hypogastric artery. This is effected by dividing it at the lateral corner of the bladder and pulling it back up to its origin from the anterior trunk of the internal iliac artery, where it is ligatured and again divided.

The fossa is filled with a wad of fatty tissue, which has a rat-tail extension downwards and forwards almost as far as Poupart's ligament. The glands lie in this fat, and the obturator nerve which traverses it must be gently disengaged, care also being taken not to injure the obturator artery or veins.

When the surgeon comes to deal with the fossa on his side of the table he should cross to the other side so that he can see what he is doing; otherwise he stands in danger of injuring the tributaries of the internal iliac vein which run in the same line as the hypogastric artery, but half an inch or more deeper down. This track of tissue is a danger zone and one should keep clear of it unless it is infiltrated; for if these veins, which form a regular plexus, be opened, free bleeding follows, very difficult to arrest, and much time and blood is lost.

DURATION OF THE OPERATION.

Every operation has an optimum time-period for its accomplishment, the duration of which depends on the nature of the various risks of the operation, and the proportion they bear to the total risk. Thus, in the case of an operation whose principal risk is the bleeding accompanying it, or the effect of the anæsthetic, or the exposure of large raw surfaces, the shorter the time of its performance the better. On the other hand, in procedures whose chief danger lies in the possibility of a suture line not holding, or of infection of the operation area from adjacent areas already infected, or of injury to vital organs or parts in its immediate neighbourhood, meticulous accuracy in suturing, painstaking antiseptic technique, and delicate dissection are the essentials for success, and the time taken counts for little in comparison.

As regards the effect of tissue injury, it is important to remember that it depends not only on the actual amount inflicted, but also on the time-period over which the infliction is spread. Thus, a pound weight dropped on a man's head from a height of a yard would certainly stun him; whereas a half-ounce weight dropped from the same height 32 times at intervals of a minute would merely give him a sore head. Traumatic shock is the result partly of tissue injury and partly of tissue exposure; and of these two factors the first (other things being equal) is minimised by slowness, and the second by speed. The optimum time-period of performance of an operation will therefore be most often arrived at by the surgeon who strives to reconcile the conflicting claims of the several risks involved in it, and not by him whose object is merely to get through it as fast as possible. For Wertheim's operation, entailing as it does much tissue exposure and more or less continuous oozing of blood, it is obvious that a certain rapidity of performance is always desirable, and more especially in those cases to which I have referred in which the oozing is profuse. Assisted by Louis Rivett I once performed it from start to finish in 27 minutes, and on several occasions I have accomplished it in under 40 minutes. Nevertheless, I have of recent years made speed less of an objective than I used to do and concentrated more on accuracy of detail, to the betterment of my results. It is impossible to lay down a rule because cases vary so much in difficulty, but on the average I should estimate that the operation should take about an hour and a quarter. The surgeon should, however, have at his command sufficient dexterity to shorten this time very materially if in any particular case it is desirable.

Immediate After-Treatment.

Some patients are considerably shocked by the time they leave the table, but a much larger number develop symptoms of shock an hour or more afterwards as the effect of the ether wears off. To combat shock I used to fill the abdominal cavity with warm saline just before finally closing it, but this is only practicable if the end of the vagina has been sewn up. Saline venous infusion is of the greatest value if it is carried out *immediately* after the operation, but the longer the time allowed to elapse before it is resorted to the less good will it do. I therefore nowadays often administer it on the table, even in cases whose condition appears quite satisfactory, so as to anticipate the supervention of shock symptoms some time later. Blood transfusion has proved of enormous benefit, especially in cases of delayed shock for, unlike saline infusion, which only gives good results when administered immediately, it acts equally well some hours after the operation.

Continuous saline infusion into the cellular tissue is a good adjunct to venous infusion and may be ordered in those cases in which the patient's condition is good enough not to need venous infusion. An electrically heated cradle should be employed during the period of shock, and camphor is the best stimulant to use.

Recurrence of the Disease.

About 68 per cent. of all recurrences occur before the end of the second year, and 90 per cent. before the end of the fifth year. Of the 107 recurrences in the series I am presenting here, 21 occurred in the lower pelvis—that is to say, in the remains of the vagina, the bladder, or the rectum; 49 in the upper pelvis, chiefly in the cellular tissue along its side walls, or in the pelvic bone itself, and in the track of the iliac vessels; 28 in the abdomen, chiefly in the tissue behind the peritoneum, or in the vertebræ; 7 in the lung; 1 in the brain; and 1 in the skin as multiple nodules. In this case the growth was a pure columnar-celled adenocarcinoma, which is uncommon in the cervix. Of the 284 cases, only 10 had this type of growth, though a tendency to columnar formation is not infrequently seen in patches in many carcinomas of the cervix, and I have seen an alveolar arrangement in the primary growth with an adenomatous arrangement in the secondarily affected glands.

Secondary growths are very rarely susceptible to further operative treatment and practically only when they occur in the remains of the vagina; of the few of that sort that I have removed all the patients died of further recurrence. I have on rare occasions, when the patients were quite young women, conserved an ovary. In two of these cases the growth recurred in the ovary left behind, and in one of them I was able to remove it. The operation was performed over ten years ago and the patient is still alive!

A considerable proportion of the patients who exhibited recurrence were treated by radiation, chiefly by X rays, but some by radium, but not one was saved.

Radiation as an Adjunct to Operation.—The vast bulk of the patients operated on by me received no treatment by radiation beforehand. Of the few that did, with a view to "making the growth operable," every one has died, either as the result of the operation or by rapid recurrence afterwards. I am of opinion that radiation, if a considerable interval has elapsed between it and the operation, increases the surgeon's difficulties, and that in those cases in which it has been claimed that it turned an irremovable into a removable growth the case was really operable before the radiation, only the surgeon did not know it. Moreover, I believe with Heyman that the chances of radiation producing a good effect are largely spoilt if the part radiated or to be radiated is subjected to operative disturbance, because the tissue reaction, to which equally with the damage done to the tumour cells the good effects of radiation are to be ascribed, is interfered with.

None of my patients has been treated by radiation after the operation, except in a few cases in which I was obliged to leave gross masses of cancer (either in the form of malignant glands or infiltrated cellular tissue) on the side wall of the pelvis because they were irremovable. These patients were treated by X rays directed to the area where growth was known to remain, but not in one single instance did the treatment prevent the cancer pursuing its fatal course.

Five-Year Survivals.—Of the 284 operations, the results of which I present to you to-day, 110 of the patients were free of recurrence five years after their respective operations. The relative cure-rate, or the proportion of five-year survivals to the total number operated on, is therefore 38·7 per cent., not deducting from the count the 20 patients either lost sight of or died of other diseases; or, in other words, counting them as having died of cancer. If, however, these 20 patients be deducted from the count as is statistically more accurate, the relative cure-rate is 41·6 per cent.*

Ten-Year Survivals.—Five years' survival after the operation cannot, however, be considered as absolute proof of cure, since about 10 per cent. of the total recurrences occur between the fifth and tenth years. Up to the end of 1919, or ten years ago, I had performed 181 operations whose results on the basis of ten years' survival are as follows:—

Died of operation	31 (17·1%)
Recurred before 10 years	67
Lost sight of before 10 years	19
Died of other diseases before 10 years ..	9
Ten-year survivals	55
	181

Counting as though they had died of cancer the 28 cases lost sight of or died of other diseases before ten years, the relative cure-rate (real cures now) is 30·3 per cent., or deducting from the count the aforesaid 28 cases, 36 per cent.

Effect of Glandular Involvement.—The chief advantage of Wertheim's operation over every other form of treatment, the results of which have up to now been published, is that it gives a definite chance of permanent cure, even to patients in whom the regional glands are cancerous by the time they seek advice. Of the 284 cases operated on by me from 1907 to the end of 1924, the regional glands removed at the operation were cancerous in 124 and not cancerous in 160. The gland involvement-rate was therefore rather over 43 per cent.

The results in these two groups of cases are as shown in Table I.

TABLE I.

—	Glands free.	Glands involved.
Died of operation	19	28
Recurred before five years ..	47	60
Lost sight of	7	5
Died of other diseases ..	6	2
Five-year survivals	81	29
—	160	124

The five-year survival-rate for the gland-free group is therefore 49·9 per cent. without deductions (see back) or, with deductions 55·1 per cent.; whilst for the gland-involved group it is 23·3 per cent. without deductions, and 24·7 per cent. with deductions. My ten-year figures show a similar difference. The chance of cure, therefore, in a case in which the regional glands are not involved, is rather over twice that of a case in which the regional glands are involved, but the difference to my mind is less to be wondered at than the fact that even when the operation is carried out against such a handicap as already involved glands, one patient in five is cured by it.

---

* The former method prevents concealment of unfavourable cases.

THE ABSOLUTE CURE-RATE.

The absolute cure-rate is the proportion of five-year survivals to the total number of patients presented to the surgeon. As regards myself, this total number has to be estimated, for I have no actual figures covering the period 1907–24. Between the years 1907–11 Comyns Berkeley and myself, who were working in concert, were able to keep accurate count of all the cases seen by us, both at Middlesex Hospital and Chelsea Hospital for Women, for we were the only surgeons performing the operation in those hospitals at that time. During that period 112 cases presented themselves to us, and of these we operated on 70, or 63 per cent. From 1911 onwards it became increasingly difficult to keep such a count, because our colleagues at Chelsea had begun to do the operation too, whilst I was presently translated from the out- to the in-patient staff, so that the cases coming to the hospital were no longer entirely presented to us; moreover, Middlesex Hospital (to which on account of its incurable cancer wards an undue proportion of advanced cases had always been sent), became known as a radium centre, and the number of these became so increased that the patients presenting themselves no longer constituted a fair sample of the cases of carcinoma of the cervix in the community at large. We therefore gave up as futile the task of disentangling the cases in which we determined the treatment from those in which the treatment had been determined by others, and in all our subsequent communications continued to reckon our operability rate as 63 per cent., and to deduce the total number of patients seen from that figure.

In the figures now to be given (Table II.) the total number of cases seen by me during the period covered by the series is reckoned on the basis that my operability rate has remained at 63 per cent. throughout the period the series covers, though in fact I believe it to have been materially higher in the later years.

TABLE II.

—	Cases seen.	Cases operated.	Five-year survivals.	Absolute cure-rate (per cent.).
No deductions ..	450	284	110	24·4
Deducting cases lost sight of and died of other diseases ..	430	261	110	25·5

Though I have not been able to keep actual count of all the cases I have seen in my hospitals, I *am* able to give the number I have seen in my private consulting-room. Between January, 1910, and the end of 1920 I saw privately 140 cases of carcinoma of the cervix, and of these I operated on 113 (some in hospital and some in nursing homes) so that my operability rate for these patients is 80 per cent. Up to the end of 1924 I had seen privately 106, and of these I operated on 83, or 78 per cent. The results obtained from this *group of cases are as follows:—*

Cases seen	106
Cases operated	83
Operability rate (per cent.)	78
Operative mortality (per cent.)	9·6
Five-year survivals ..	38
Relative cure-rate (per cent.)	48
Absolute cure-rate (per cent.)	37·5

Both the "rates" are without deductions.

It may be argued that these patients, nearly all of whom were sent up to me by various medical men, form a selected group in whom the disease was early or relatively early. The percentage of gland-involved cases in the group is, however, 40 per cent., which, though less than the figure 43 per cent. which obtains in the whole series, is sufficiently high to show that in average advancement the growths were not very greatly different. On the other hand, this group of patients were in financial and social position above the average of those of the whole series and therefore as regards their general condition were superior material for operating upon. The better results obtained were chiefly due to this factor and substantiate what I said earlier in this paper—that the chief risk of the operation lies less in its severity, per se, than in the poor average condition of the patients. My chief reason, however, for giving the figures relating to this group is to show that in assuming my general operability rate for the whole of the series under consideration to have remained the same (63 per cent.) as it was when actually calculated in the four years 1907–10, I have rather under- than over-estimated it.

Comparing the results I have obtained from my series as a whole with the average results of the small group of highly skilled surgeons who have performed the operation on a large scale and also kept count of their figures, it is seen that as regards the proportion of five-year survivals to the total number of patients operated upon, my results are about the same as the average, whilst as regards the proportion of five-year survivals to the total number of patients seen they are rather better.

TABLE III.

—	Cases seen.	Cases operated.	Operability rate (per cent.).	Operative mortality (per cent.).	Five-year cure-rate (per cent.).	
					Relative.	Absolute
Wertheim	979	450	46	19	41·3	19
Mayer ..	545	343	63	19·9	31·2	19·6
Stoeckel ..	350	243	70	18·9	35·4	24·6
Zweifel ..	413	251	58	7·6	47·8	27·6
Franze ..	473	383	81	15	37	28
Bumm ..	263	179	68	12	43	28
Bonney ..	450	284	63	16·5	38·7	24·4
Fletcher Shaw..	200	106	53	21·7	37·8	20
Total ..	3703	2239	60·4	16·4	38·7	23·4

It may therefore roughly be stated that the operation when carried out by surgeons skilled in its performance really *cures* (by that term meaning survival for ten years) rather over one in three of all the patients operated on, and rather over one in five of all the patients seen.

FUTURE OF THE OPERATION.

In a paper quite recently published[1] I showed that the results I had obtained by Wertheim's operation were not only numerically better than any yet claimed for radium, but the number of five-year survivals achieved by the operation was obtained from a much smaller percentage of cases treated, for the radiologist, in order to obtain a certain number of cures, has to treat 96 per cent. of the cases seen by him, whilst the surgeon obtains a rather greater number from only 63 per cent. His remainder (excluding 4 per cent. too advanced to be treated by any method) can be treated by radium and a small number of cures obtained this way; whereas the radiologist has no such surplus, having used up his entire stock of available material in obtaining his results. The conclusion I drew was that at the present time the largest number of cures of carcinoma of the cervix were to be obtained by operating on the operable cases and treating the remainder by radium. I further showed that the advantage of surgery over radium lies in the former being able to cure a proportion of the cases whose regional glands are already cancerous by the time they seek advice, whereas in the case of radium all these patients are beyond its scope. The inability of the radiologist to distinguish beforehand the gland-involved from the gland-free cases presented to him is a great drawback, for it compels him to treat a number of patients not only uselessly but to the exclusion of the chance that surgery affords. The truth of the matter probably is that in certain cases surgery, and in others radium, would give the best chance of cure, each case being a law unto itself in this respect, but our investigatory methods are too coarse and imperfect to enable us to discriminate accurately.

---

[1] Proc. Roy. Soc. Med. (Sect. Obst. and Gyn.), 1929, xxii., 53.

This is the position at present, but how long it will continue so remains to be seen, for the control of the forces of radio-activity is yet in its infancy and the future may see the power capable of disrupting the very atom into its component parts harnessed and directed to a degree only dreamed of to-day. We have, however, to deal with things as they are, not as they may be, and hence I deprecate as altogether premature the appeals that have been made to the younger generation of gynæcological surgeons not to embark on the operative treatment of cancer of the cervix, but instead to take up radium therapy, the present estimate of whose value in this connexion is founded solely on figures from abroad. Not until the results of reliable workers in this country are available shall we be in a position to properly appraise its effects, for it does not follow that the same measure of success attending a method of treatment in one country is necessarily attained when it is carried out in another country.

It has been objected against Wertheim's operation that its difficulty is such that only a few individuals are capable of performing it with success, but that is not the case. There is nothing in the operation that any surgeon of first-class aptitude cannot master, provided he will take the trouble to learn the technique from someone who has already mastered it. We hear a great deal nowadays about the necessity of radium treatment being confined to a relatively small number of experts in order that the best results shall be obtained, but no such demand has ever been made for surgical treatment, although the necessity was and *is ten times greater.*

The younger gynæcological surgeon of to-day does not start where I started, still less where Wertheim started. It is not now a matter of acquiring technical experience at the expense of his patients; the technique is already stereotyped, all he has to do is to serve an apprenticeship in it, follow it, and later on improve upon it. Nor is the extent of Wertheim's contribution to surgery only to be computed on the number of women cured of cancer as the result of it. The surgeon practising the operation is himself benefited, for besides arriving at a knowledge of the anatomy of the female pelvis obtainable in no other way, he gains a greatly increased confidence in the capabilities of his art and hence becomes a better exponent of it.

A Review

OF THE TREATMENT OF

INTRACTABLE DISCHARGE FROM THE NASAL SINUSES.

An Address delivered to Post-graduates at the Central London Throat, Nose and Ear Hospital on Jan. 24th, 1930,

BY A. LOWNDES YATES, *M.C.*, M.D. LOND., F.R.C.S. EDIN.,

ASSISTANT SURGEON TO THE HOSPITAL AND TO THE EAR AND THROAT DEPARTMENT, PRINCE OF WALES'S GENERAL HOSPITAL, TOTTENHAM.

WHEN nasal discharge becomes intractable and does not yield either to Nature or to ordinary treatment it is necessary to review the case in order to discover the cause of the intractability; the common cold furnishes us with the most simple example of pathological change which affects the nasal mucous membrane. These changes may be divided into three.[1]

THREE STAGES IN PATHOLOGICAL CHANGE.

Stage 1.—At the beginning of a cold the nasal mucous membrane reacts to the infection by an increase of secretion from its mucous glands.[2] If in this stage the mucus is examined microscopically it will be seen to contain a quantity of micro-organisms, the mucus being, in fact, secreted with the object of destroying them. If it does not destroy them the pathological process passes to the second stage.

Stage 2.—In the second stage Nature has given up the attempt to kill the micro-organisms by means of mucus, the increasing toxins from these micro-organisms paralyse the secretion from the mucous glands, and the nose becomes for a short period dry. The micro-organisms, thus partially deprived of moisture, have difficulty in obtaining nourishment, but their toxins pass through the nasal mucous membrane into the blood stream and in the severer cases the reaction they call forth produces fever. This reaction also produces immunity in the blood stream to these toxins and, when immunity has been established, the temperature falls. The irritation of the mucous membrane by the micro-organisms has during this period produced an outpouring of serum and leucocytes which together tend to destroy the micro-organisms.

Stage 3.—The reactive stage. When the destruction of the micro-organisms has proceeded far enough for mucus to effect their final removal, the mucous glands begin to secrete again, and in this stage the discharge is generally very free. Microscopically this discharge consists of mucus often containing many leucocytes, generally containing desquamated epithelial cells and sometimes micro-organisms.

LEUCOCYTIC AND SEROUS TYPES OF COLD.

There are, I find, two types of cold, the leucocytic type in which the micro-organisms cause leucocytes to be attracted into the mucus where they ingest the *micro-organisms*; and the serous type in which the micro-organisms are of a different type in that they *do not cause* leucocytes to pass into the mucus, and are destroyed by immune bodies excreted in the serum.

These two groups appear to correspond with what is known regarding general immunity, for there are certain micro-organisms which produce immunity and for which antisera can be manufactured, while there are others for which sera cannot be prepared for they produce no immunity in the blood. We find these two main groups clearly demarcated in the two types of cold.

The common cold not infrequently becomes intractable by reason of excess of inflammation in the nose. The leucocytic type of cold when it becomes intractable does so on account of sinusitis and the main symptom which the patient suffers is that of pain. This is often severe and sometimes incapacitates. It may be necessary to have resource to treatment for this case, and of the various treatments which we have at our command, cocaine in 5 per cent. solution in saline stands first. We spray the nose with this and try to cause the mucous membrane to contract sufficiently to permit the contents of the sinus to be naturally discharged. If this is not successful, it will be necessary to wash out the sinus. Now I have one rule in connexion with the treatment of acute sinusitis which I think is of paramount importance—namely, that in no circumstances do I wash out an acute sinus with a watery solution. We can assess what happens when we do so by mixing the contents of such a sinus with saline. We find that micro-organisms previously retained within the leucocytes, or in the mucus and serum, are liberated. Nature has produced an antibacterial fluid in the sinus and if we dilute it, it loses many of its antibacterial properties and the washing out of such a sinus with a watery fluid is, I think, a dangerous practice. We can, however, aspirate the sinus through two catheters introduced within its lumen, or we may wash it out with oils, of which medicinal paraffin is by far the best.

The serous type of cold when it becomes intractable does so on account of desquamation of the epithelium and of toxic absorption. It is comparatively rare to meet with pain from sinusitis in this type of cold, although the sinuses may be infected, for the pain is generally of the toxic type which affects the back and joints. If we examine the discharge in the period of reaction we find that the mucus contains large quantities of desquamated cells. Before recovery can take place these cells will have to be replaced by the regrowth of the nasal epithelium, and until they are replaced toxic absorption in some degree can continue. The treatment of a case of this type is by oily douches. In no circumstances should watery douches be employed for they will spread infection to portions of the nasal mucous membrane in which the epithelium is becoming re-established, and thus prolong the cold and, moreover, will give rise to an increase in the degree of toxic absorption. Further, should the infected watery fluid pass through the Eustachian tube, the epithelium of this may desquamate, and the cilia being absent from the deeper epithelial layers, there is no method of removal of the micro-organisms which will spread along the tube and tend to cause acute otitis media.

PRODUCTION OF SINUSITIS.

Reference has been made to the two main types of cold, and it is clear that they may in many cases infect the nose synchronously. In such a case where leucocytic and serous reaction are present at the same time, neither of these reactions seems to be generated to its full extent, and recovery is delayed. This is the type of cold that produces sinusitis with toxic absorption and it is by far the most difficult cold to deal with. In this connexion we have to remember that in the early stages of a cold of this type the body has but little immunity to certain of the organisms. If it becomes necessary to open any sinus under such conditions, the veins within the bone are easily infected and a spreading osteitis may occur, sometimes with most disastrous consequences. In the treatment of a sinusitis complicating a cold, every effort should be made to avoid inflicting any trauma on the bone, and if it becomes necessary to open any sinus because we cannot pass a catheter within it, it is most essential that the opening of the bone should be made through an area in which large intra-osseous vessels are not present. Such areas exist in the lower wall of the frontal sinus[3] [4] [5] and far back on the naso-antral wall beneath the inferior turbinate.

Under suitable conditions a mild cold recovers by itself, or as a result of palliative treatment of the nasal mucous membrane. The results of palliative treatment may, however, easily be annulled if reinfection constantly occurs. Such reinfection may be air-borne or finger-borne. Air-borne infection may occur from other people's septic teeth as, for example, when a mother has pyorrhœa and constantly infects her child, or when a clerk has well-marked nasal or dental sepsis and infects the air around him. On the other hand, reinfection in children constantly occurs when they introduce their fingers into the nose. In a few cases patients will reinfect their nose after an antral operation by failure to sterilise the cannula which they employ for douching.

The nasal mucous membrane in the stage of recovery from a cold regrows the epithelium which has been desquamated during the active process, and also forms additional new mucous glands if the state of recovery is prolonged, and the presence of micro-organisms in the nose producing active inflammation tends to produce new fibrous tissue in the mucous membrane. Should the process of recovery be prolonged, one of these three factors will predominate. If mucous glands grow in excess we term the process hypertrophic rhinitis, though here the congestion may produce an actual increase of the periosteal bone so that the hypertrophy may be of bone and mucous membrane. If, on the other hand, fibrous tissue has been produced in great excess a fibrotic type of atrophy will follow. If the desquamation has been excessive, a crusting type of atrophy will be found and toxic absorption will be present in considerable degree with resultant manifestations in the joints,[5] or in the fibrous tissue around the periphera nerves. Deficiency of the blood-supply to the mucous membrane (such as occurs in the anæmias and in syphilis) will expedite this second type of atrophy.

We have not so far spoken of the olfactory area of the nose. This is the area above the middle turbinate, and here the secretions have a different nature in that they are watery so as to dissolve odiferous substances and thus permit them to stimulate the endings of the olfactory nerve. This area is one in which inflammation may be dangerous, for the olfactory nerves are sheathed by lymphatics which convey the lymph from the nose to the meninges.[6] Should an intractable rhinitis be present in this area, oily solutions should be employed, for these seem to prevent absorption of the toxins by these lymphatics.

CHRONIC INTRACTABLE SINUSITIS.

Theory of the "Master" Sinus.

In chronic sinusitis examination seems to prove that all the sinuses are equally infected. It is rare, however, that this is actually the case, for generally there is a master sinus which infects the others, and this sinus only is in a stage of inflammation from which it cannot recover without aid, while all the other sinuses will recover of their own accord if reinfection from the master sinus can be stopped. These cases of sinusitis differ very greatly in the amount of discharge which they emit. In some the discharge is slight in quantity. An X ray of such a case will generally show no alterations in the sinuses, but should we have the good fortune to examine such a case when it is recovering from a cold, the master sinus recovers less quickly than the others, and this alone will be dull upon the radiograph. In other cases where the sinusitis is of high degree the character of the secretion aspirated from the sinuses may indicate the master sinus, for in the master sinus micro-organisms may be seen free in the secretion, while in the other sinuses they are absent, or are contained within the leucocytes. The treatment will depend on the type of sinusitis we are dealing with, but in all types the same general rules of treatment will apply. These rules may be expressed as follows. We wash out each infected sinus and note if washing out produces an improvement. If on each washing out there is considerably less discharge this process is continued until cure results. Whether we should wash out with oil or with water will depend on the type of case with which we deal. If, on the other hand, washing out produces only temporary improvement, we either catheterise the sinus and tie in a catheter through which the patient washes out the sinus as an in-patient, twice a day, or, in the case of the antrum, we open the antro-nasal wall so as to permit the patient to pass a catheter twice a day and so wash out the sinus. The type of patient will, to some extent, determine whether we operate or no. In children one lavage will generally cure the case and this is best done under general anæsthesia, which will also give an opportunity to remove infected adenoids or tonsils. In nervous ladies, some small opening should be made, under general anæsthesia, such as will permit them to wash out the sinus. In other persons it is generally possible to do all that is required under local anæsthesia, although on the first occasion it may be wise to give gas in addition, for after the first puncture the instrument can be introduced into the sinus without discomfort under local anæsthesia alone.

Atrophic Sinusitis and Rhinitis.[7] [8]

If there is general crusting atrophy of the nasal mucous membrane, this is a contra-indication to the performance of all operations excepting those of urgency, for the devitalised tissues have but little power of recovery and general infection may quite readily ensue. Patients with the fibrous type of atrophy, on the other hand, stand intranasal operations well in the rare cases when surgical interference is required. As regards treatment of atrophic sinusitis and rhinitis, the fibrotic type as a rule requires an oily douche to guard the mucous membrane from undue evaporation; the crusting type requires much more active treatment in that the crusts must be removed by means of forceps, or if need be by hydrogen peroxide, after which it should be kept free from crusts and treated as if the condition were an eczema. Calamine lotion may give good results, but in some will cake into hard masses. Should this be the case ointments of calamine in a base of lard, or vaseline may be substituted, while sometimes ichthyol and glycerin give good results. In every case the master sinus must be sought and dealt with.

Radiography.—The atrophic type shows no dullness on the skiagram to which the bones are more readily transparent than in the normal, and the hypertrophic type is almost always accompanied by thickening of bone which thus casts denser shadows on the radiograph. The presence of bone which is very penetrable to X rays will make us consider the question of operation with especial care, for the reaction of the tissues except in the fibrous type is likely to be slight.

Microscopy.—If we examine the discharge under the microscope and see free micro-organisms in the fluid, we shall, as a rule, do well to postpone operation until, as a result of treatment, such a degree of recovery has taken place that free micro-organisms are absent from the discharge. If we cannot succeed in this our operation should be limited to the smallest removal of the bone that will permit the patient to wash out the sinus for himself.

Hypertrophic Sinusitis and Rhinitis.

If there is hypertrophy of the mucous membrane of the nasal air-way the resistance of the intranasal structures is high; an operation can be done with practically no risk whatever. There are certain cases of sinusitis in which the degree of hypertrophy is so great that we may feel certain that intranasal operation and douching out the sinus will not effect a cure. In such a case there may be polypi and these may be present in the antrum, where their presence may be demonstrated by a radiograph after an injection of a suspension of finely powdered bismuth oxycarbonate into the antrum. This method will also serve to show the existence of a carcinoma of the antrum. Lipiodol should be substituted for the bismuth in the sphenoid or the frontal sinus. If we find sinusitis of this hypertrophic type we should open the antrum from the outside and thus remove the polypi. If the polypi are in the frontal sinus it will be necessary to open this after the methods originally popularised by Howarth and by Kisch. It is rare to find polypi in the sphenoidal sinus but they are common in the ethmoid, and as they generally grow from bone which is devitalised and carious, it is in these cases necessary to exenterate the ethmoidal labyrinth.[9] In any intranasal operation the most gentle technique which is consistent with thoroughness will produce the quickest and most lasting cures.

FACTORS IN PRODUCTION.

Rôle of Dental Sepsis.—Abscesses at the root of the molar teeth will not infrequently infect the antrum. When they do so the sinusitis may be one of two types: either the abscess actually bursts into the antrum which undergoes rapid inflammation and becomes filled with fœtid pus, or the abscess causes periostitis beneath the antrum and the mucous membrane thus becomes inflamed. It is of paramount importance to deal with every form of dental sepsis complicating sinusitis and it will not be sufficient to examine the teeth superficially, for in several instances the dental sepsis has been revealed only by a skiagram.

In other cases pyorrhœa may produce general toxæmia, or may indirectly cause infection of the antra. In yet other cases the pyorrhœa may cause infection of the air around the patient, and he may infect not only other people but himself. A form of atrophic rhinitis from this cause is not unknown.

Rôle of Nasal Obstruction.—If nasal obstruction is present it may diminish the opening of the nasal sinus so that it affects the drainage of this into the nose. In such a case cocaine will generally free the opening temporarily and should be used in all acute conditions. It is, however, necessary to free the obstruction by some form of operation in cases of sinusitis which do not improve. Nasal obstruction may play another part in producing sinusitis in that the tortuous air-way which a deflected septum produces causes a considerable area of the mucous membrane to be out of the inspiratory air current, as a result of which the rôle of dust removal falls upon a similar area of mucous membrane which tends to become more easily inflamed. Sinusitis and rhinitis can then be produced with a less degree of infection than would cause the same condition were all the nasal mucous membrane presented to the air current in the normal manner.

ENVIRONMENT AFTER OPERATION.

We shall do well in treating sinusitis to consider the environment to which the patient will be going after operation. If he is going to a dusty climate, such as may be met with in certain portions of Australia or South Africa, every effort should be made to conserve as much as possible of the mucous membrane. If we remove the middle turbinate and portions of the inferior we shall not leave enough mucous membrane to deal with the environment of dust, and when a mucous membrane is subjected to more trauma than it can resist it will become atrophic, and this is the fate of many operations designed to give the best results in England when the patient moves into a dusty climate such as those which we have mentioned.

Disorders in the General Health.[10, 11]—It is not infrequent to find cases of intractable sinusitis which recover spontaneously on improvement of the general health, or in which success by local treatment or by surgery can only be obtained when the patient's general condition can be improved. In this connexion we have had to consider causes of toxæmia other than those emanating from the infected sinus. Such conditions may be met with in the bowel as a result of chronic constipation or appendicitis. In considering a case of sinusitis, therefore, it is necessary to avoid the errors which arise from considering only the region of the nose. Many a cold which showed signs of becoming a chronic sinusitis has been cured by a timely dose of castor oil. Many a case of chronic ill-health apparently due to sinusitis has been cured by dealing with the appendix or the gall-bladder. In older people the presence of chest conditions has frequently led to failure to recover from conditions in the nose, while cardiac conditions may not infrequently predispose to nasal inflammation. Active tubercle and syphilis must always be sought for in patients whose health is poorer than the clinical signs will warrant.

As regards the general state of toxæmia met with in certain of these patients, it would appear that liver diet, or the extract administered hypodermically, is extremely valuable in raising the resistance during treatment.

The condition of the skin is of considerable importance. There can be no doubt that persons with an acid skin stand operations badly, though whether this be by reason of a diminished elimination of certain poisons by the skin, or because they have some degree of acidosis, does not seem clear. Certain it is that the removal of all secretion from the skin by frequent washing is important in patients in whom the powers of resistance are diminished.

As regards acidosis, or rather the compensation for the acidosis, we meet with this condition so frequently in toxæmia, and it is so important as an agent in preventing the recovery of intractable sinusitis, that one feels that the compensated acidosis and the toxæmia must in some way be dependent on each other. Certain it is that if we give a patient a sufficient quantity of sodium bicarbonate to render the urine slightly alkaline, that immunity is often re-established where previously the patient suffered from toxæmia. It is good practice, therefore, to assess the degree of acidosis which is compensated and to remedy this during the period of treatment. The use of alkalis must not be long continued or phosphatic stones might possibly be formed within the hilus of the kidney or bladder.

As to the use of vaccines in these cases, they are sometimes very successful if given in a special way. The method that I advocate is as follows. A culture is made from pus *sucked from the interior of a sinus*, and a vaccine is prepared from it. A very small dose of vaccine is then injected into the superficial layers of the dermis, and not hypodermically. This forms a bleb upon the skin, and if the vaccine contains the toxins which are circulating a reaction similar to that of von Pirquet occurs. By the degree of reaction the appropriate dose of vaccine may be gauged. This is a matter of some importance, for an overdose of vaccine can debase immunity for a considerable period. When the appropriate dose has been discovered, vaccines may be given hypodermically with an occasional intradermic dose to estimate the degree of reaction to the vaccine. There are certain types of sinusitis and rhinitis in which violent and painful reactions of the nasal mucous membrane occur at quite irregular intervals, and during an attack the mucous membrane is vermilion red. These are probably cases of susceptibility to some air-borne vegetable or animal protein, together with the ordinary inflammation of a sinusitis. The mucous membrane in these conditions permits absorption very readily, and if a tiny but increasing dose of vaccine is sprayed into the nose the mucous membrane sometimes reacts to this and a local immunity may be thus established. In passing it may be mentioned that cases of this type are entirely unsuitable for any sort of operation other than simple lavage of the sinuses.

SUGGESTED LINES OF TREATMENT.

If the condition is one of atrophy with crusting in the nose and often with offensive smell, the following line of treatment will often give most excellent results. The nose should first be cleansed of crusts and discharge with hydrogen peroxide and if necessary the crusts should be removed with forceps. When it is clean it may be packed with gauze, soaked in the following solution and this retained in the nose for 24 hours.

R	Iodoform	grs. 30.
	Bismuth subnit. ..	grs. 60.
	Paraffin liq. ..	ad oz. 1.

After removal the nose is cleansed twice daily, first by douching with saline, then with

℞	Hydrogen peroxide ..	vols. 20, oz. 1.
	Normal saline ..	ad oz. 10.

This should be warm and the strength of the peroxide should be increased until slight stinging follows its application. The nose should then be vigorously blown and the following solution swabbed into the nose with wool:—

℞	Calamine	grs. 60.
	Glycerin	dr. 1.
	Aqua	ad oz. 1.

This treatment, which is based on treating nasal atrophy as if the condition were one of eczema, gives good results only in so far as it removes the greater portion of the inflammation from the portion of the nose which lies within the nasal air-way. It does not however reach the sinuses, and if, as generally, these are affected they must be washed out. Saline may first be used for this but if it fails, as commonly, to stop discharge, a 1 per cent. solution of argyrol may be tried. A weak solution of iodine made by adding a drachm of the French tincture to a pint of saline may be used instead of the argyrol, and alcohol may be usefully added to this if the discharge from the sinus does not cease. My own belief is that we should never operate upon a case of atrophic rhinitis unless forced to do so by some urgent and acute complication, which is fortunately very rare. If the sinus condition does not clear up with treatment it is, I think, good practice to use formalin vapour as a means of treatment. The use of this is based upon the fact that workers in trades in which formalin is used do not catch colds and often lose their nasal infection when they start employment of this nature. We can copy this by placing a little 1 per cent. formalin in the patient's bedroom and allowing it to work *while he sleeps, having first assured ourselves that* the patient during the hours of sleep breathes through his nose. The formalin should never be so strong as to make the eyes water. Many cases will clear up when dealt with by this means, though some are irritated.

There is one type of atrophy which deserves special mention—namely, the type which follows operation and affects small areas of the nose and proves intractable to treatment. The atrophy here is incomplete and can as a rule quite readily be cured by application of a dull heated actual cautery. The most that we can do with any case of atrophy is to produce a functionless and fibrous type of mucous membrane. Discharge upon this membrane is extremely small in quantity but tends to dry and to form crusts. Such patients should therefore be provided with an oily douche such as the following:—

℞	Ol. pini	♏ xxx.
	Paraffin liq. ..	ad oz. i.

This should be instilled daily into the nose with a medicine dropper; sprays do not yield sufficient oil to serve the needs of such a mucous membrane.

In acute cases a masterly inactivity gives the best results provided that we raise the general resistance. It is good practice to combat the acidosis by means of alkalis or fruit juice, for the temperature frequently falls and the local condition improves directly the urine has become alkaline. If this fails we may douche the nose with oils such as liquid paraffin, but never with a watery solution. If there is reason to believe that pus is retained within a sinus we should contract the mucous membrane with cocaine and try to cause the pus to escape. If this fails I personally try to introduce soft catheters into the frontal or the sphenoid sinus. These are stiffened with wire which is withdrawn when the catheter is in position. The sinus is then douched with oil and generally clears up.

If there is an empyema of the maxillary antrum this should be washed out by making a very tiny opening well back in the nose beneath the inferior turbinate. Oil should be used for washing out. If the antrum is infected by a carious tooth this should on no account be removed during the acute stages of the inflammation lest sepsis spread to the diploë of the alveolus.

Cases in which an acute sinus condition has complicated influenza must be watched for some time afterwards with considerable care, lest an intractable rhinitis manifests itself later.

Hypertrophic Rhinitis.—In this condition we have evidence that the mucous membrane has reacted to the infection. We have two types of this complaint, the infected and the uninfected. In the infected type we can find free micro-organisms in the discharge, or micro-organisms in the leucocytes. These cases show for the most part intermittent symptoms. They should be treated with respect. The master sinus should be found and carefully washed out. If the discharge becomes less each time the washing out will cure the case. If the discharge does not decrease with the washing out, we shall have to wash out more frequently and, therefore, must perform an operation in order to permit the patient to do this for himself. This is the reason of opening the antrum in the majority of cases. The frontal sinus and the sphenoid demand severe operations to remedy discharge within them. Every effort should therefore be made to clear up this discharge by palliative measures. Similar remarks apply also to the ethmoids. We should always bear in mind the possibility that a dental sepsis is keeping up discharge.

Non-infected Type.—In this the mucous membrane has killed the micro-organisms and continues to discharge mucus from the glands which have been produced in extra numbers during the period of inflammation. These simple uninfected cases are readily diagnosable by the microscope, for the mucus contains no micro-organisms and few, if any, leucocytes. A simple nasal douche will in course of time cause the discharge to disappear.

Obstructive Type.—The nasal air-way may be obstructed on one or on both sides. The tortuous characters of the abnormal passages will throw the work of removal of micro-organisms on to a very small area of the mucous membrane. This may become inflamed and inflammation may readily spread to sinuses. This will not then get well unless the cause of this same inflammation is removed and the tortuosity of the abnormal passages removed by resection of the septum and by moulding the turbinates into more normal positions, removing such portions of them as are greater than will be required.

ALKALOSIS IN CONGENITAL HYPERTROPHIC PYLORIC STENOSIS.

BY MONTAGUE MAIZELS, M.D., M.R.C.P. LOND.,
PATHOLOGIST, INFANTS HOSPITAL, WESTMINSTER;
CATHERINE B. McARTHUR, M.B. LOND.,
ROBERT MOND RESEARCH STUDENT, INFANTS HOSPITAL;
AND
WILFRID W. PAYNE, M.B. LOND.,
BIOCHEMIST TO THE HOSPITAL FOR SICK CHILDREN, GREAT ORMOND-STREET.

(From the Department of Pathology, the Infants Hospital; and the Biochemical Department of the Hospital for Sick Children.)

THE occurrence of alkalæmia in gastric and intestinal obstruction has been recognised for a decade. A summary of the literature appears in a contribution by Hartmann and Smyth,[1] and these authors submit a series of blood and urine analyses in cases of intestinal obstruction in part of the alimentary canal. Ten cases of their series were suffering from congenital hypertrophic pyloric stenosis and, of these, eight had a raised bicarbonate reserve in the blood. In view, on the one hand, of these results, and, on the other, of the commonly held view that acidosis is to be expected in this malady, it was decided to investigate all the cases of congenital pyloric stenosis occurring in the wards of the Hospital for Sick Children and the Infants Hospital from the point of view of blood reaction and salt content, and associated changes in the urine.

Methods.—The hydrogen-ion concentration of the blood was investigated by the method of Martin and Lepper[2] and the plasma bicarbonate by that of Stillman, Cullen, and Slyke modified (W. W. Payne). Blood is obtained from a puncture of the finger, ear, heel, or great toe, and allowed to flow under liquid paraffin in a tube of the type described by Martin and Lepper.[3] Potassium oxalate or heparin is used to prevent clotting, and about 0·5 to 1 c.cm. of blood can usually be obtained from one puncture without much difficulty. The blood is mixed by rotating the tube through its long axis, and is then centrifuged. The top of the collecting tube is removed and 0·1 c.cm. of plasma is pipetted into a cordite tube two inches in length. The pipette is washed out twice with 0·1 c.cm. of neutral normal saline and the washings added to the cordite tube; 0·5 c.cm. of HCl (N/100) is then added. This stage of the procedure should be completed as quickly as possible owing to the possibility of glycolysis, which may cause a low result. Subsequent manipulations may be delayed for several hours *without any alteration in the results.*

The carbon dioxide liberated by the hydrochloric acid is removed by shaking the cordite tube for three minutes under reduced pressure. This may be done by applying to the mouth of the cordite tube a rubber cork pierced by a glass tube attached to a water pump. Next are added 1·8 c.cm. of neutral normal saline and 0·15 c.cm. of phenol red solution (0·02 per cent.), and the mixture is titrated with caustic soda—N/50 (carbon-dioxide free)—to pH 7·6, using a micrometer syringe (Trevan [4]).

Before the actual titration of the plasma is commenced, the acid itself must be standardised. For this, 0·5 c.cm. HCl (N/100), 2 c.cm. of the saline and 0·15 c.cm. of the phenol red solution are placed in a cordite tube and titrated to pH 7·6. This titration must be repeated until constant values are obtained.

In calculating the results, the difference between the titration values of the HCl alone and HCl + plasma expressed as c.cm. of N/50 NaOH, is multiplied by 0·2. This gives the molar concentration of bicarbonate.

The blood chloride was estimated by the method of Claudius (somewhat modified)[5]; the urea according to Twort and Archer[6]; the hydrogen-ion concentration of the urine colorimetrically, and the urine chloride by Volhard's method, or as for blood.

The figures for normal infants are as follows: pH 7·35–7·42; plasma bicarbonate: 0·022–0·028 molar; plasma chloride: 0·096–0·106 molar; blood-urea: 0·015–0·04 per cent.

Results in Congenital Hypertrophic Pyloric Stenosis.

Of 34 cases of congenital pyloric stenosis, 28 had an increased bicarbonate reserve at some period before operation. In no uncomplicated case was acidosis present. On admission the plasma bicarbonate was found to be above 0·04 molar in 10 of the 34 cases. The pH of the blood before operation was usually increased, though not to the extent that might have been expected from the bicarbonate level. The chlorides, in general, varied inversely as the bicarbonate. The sum of chloride and bicarbonate molarities was reduced, cases with marked alkalosis showing as a rule the greatest reduction and cases with moderate alkalosis a slight reduction. It will be noted, however, that the total molarity was lower in cases with a normal bicarbonate reserve than in those with slight alkalosis. These findings are illustrated in Table I.

TABLE I.

HCO_3 molar.	pH mean.	Observations.	Cl molar mean.	Observations.	HCO_3 – Cl mean.	Observations.
–0·03	7·41	3	0·095	9	0·120	9
0·03–0·036	7·42	9	0·090	9	0·122	9
0·035–0·04	7·46	7	0·081	12	0·119	12
0·040 –	7·47	10	0·075	16	0·118	16

Examination of individual cases shows that the sum of Cl and HCO_3 molarities may be high, normal, or low. It was high in two cases, normal in six, and low in 21. Copious doses of normal saline were given to all the cases. In only seven of these have more than one pre-operation record been made. Four cases show a rise of plasma chloride, but two show a definite fall in chloride, in spite of the subcutaneous salines.

Blood-urea.—It will be seen from Table II. that the association of blood-urea with total molarity, or with plasma bicarbonate alone, is not close. This accords with the findings of Graham and Morris.[7] The post-operative changes in the blood must be *correlated with the appearance of subsequent vomiting.* In cases without vomiting or toxæmia the plasma bicarbonate became normal in from two to four days, but in the other cases the return was delayed for a week or more. In five cases the blood-urea was estimated before and shortly after operation. In all these an increase followed the administration of an anæsthetic. The increase in one case may be due partly to an intestinal infection.

TABLE II.

HCO_3 +Cl.	HCO_3 molar.	Urea per cent.	HCO_3 +Cl.	HCO_3 molar.	Urea per cent.
0·097	0·0431	0·032	0·118	0·0367	0·033
0·101	0·0397	0·149	0·118	0·0317	0·030
0·109	0·0340	0·045	0·119	0·0438	0·022
0·111	0·0440	0·050	0·119	0·0418	0·072
0·112	0·0411	0·039	0·122	0·0373	0·022
0·113	0·0317	0·030	0·122	0·0201	0·033
0·116	0·0290	0·064	0·123	0·0413	0·076
0·117	0·0437	0·050	0·130	0·0460	0·043
0·117	0·0410	0·017	—	—	—

Urine.—When the plasma bicarbonate was raised, the urine was found to be alkaline, with the exception of five cases. Before treatment chloride was absent from the urine, or present in traces only, in all except two cases, and this was true even of those cases where the plasma chloride was normal. Acetonuria was found only three times in 21 observations before operation. Therefore acidosis is absent from cases of congenital pyloric stenosis, and ketosis is rarely found. It was not always possible to gauge the level of alkalosis from the appearance of the patient. While pallor and drowsiness were common, and were suggestive of alkalosis, two of the worst cases in the present series appeared quite lively and of good colour.

Discussion.

The blood normally contains large quantities of chloride of sodium and other bases. When the acid gastric secretion occurs, chlorine ions leave the blood and an excess of base is left; this combines with CO_2, increasing the bicarbonate reserve of the blood. As the gastric contents pass into the small intestine, considerable reabsorption of chloride occurs, and the base chloride content of the blood is restored. When the pylorus is obstructed and vomiting occurs, the continued loss of HCl in the vomitus leads to a depletion of chlorine ions in the blood, and the base originally combined with them now combines with CO_2 to form bicarbonate. This relative excess of base bicarbonate is excreted to a variable extent by the kidney and the urine becomes alkaline. On the other hand, the low chloride level of the plasma leads to a retention of chloride by the kidney and the *urine tends to become chloride-free. If the vomiting* persists, loss of acid in the vomit and of corresponding base in the urine will lead to a diminution of the total amount of base chloride in the body. Further, the gastric secretion contains not only HCl but also sodium chloride, and the loss of sodium chloride directly in the vomit is added to the salt loss arising from the loss of HCl alone. This salt loss cannot be replaced from the salts of the food, because vomiting prevents their absorption.
